Mode of onset.—For some weeks (8 to 16) before the appearance of the rash the patient usually complained of weakness and dizziness. He had obstinate diarrhœa of yellowish colour and watery consistency, with passage of undigested material. The lips were dry and coated with sodden and thickened epithelium; later they cracked, especially at the angles of the mouth. There were epigastric discomfort and pain, often accompanied by sensation of a foreign body in the stomach. Salivation, pyrosis, and stomatitis were also encountered. The tongue was enlarged, fissured, and painful in the tip and sides. The buccal mucous membrane was unduly inflamed. He experienced a burning feeling in the backs of the hands, in the lips, and occasionally in the neck, with vague sensations of aching in the lumbar region and lower extremities, which often showed a transitory œdema. The appetite varied: in some there was anorexia; in others the desire to eat was excessive. The features were expressionless and the voice was low and subdued. On the whole, he presented a picture of profound depression.

The Rash.

I shall here allude only to the salient and peculiar characteristics of the rash.

The backs of the hands of the neck, previously tingling and burning, began to show an erythema, which gave the clue to the real diagnosis. This erythema might appear simultaneously or at intervals on the face, neck, hands, and feet. On all areas the skin soon became pigmented, and eventually desquamated either in fine shreddy scales or in large flakes. Extensive cracking along the natural creases of the hands frequently occurred. The character of the pigmentation varied from a very light superficial brown to a dark brown or almost black, which involved the entire cuticle. When desquamation ceased the skin of the hands became glazed and atrophic. More rarely a thickened brown pigmentation remained.

If, subsequent to the pigmentary changes ulceration of the parts ensued, the case became one of "wet pellagra." The prognosis in these latter cases must always be regarded as grave. The term "wet" applies only to the ulcerative condition of the hands and feet, and does not signify, as some observers have supposed, the presence of dropsy.

The appearances of the rash in its various stages are best visualised by the aid of the accompanying Figs. 1 and 2.

The rash is usually understood to be symmetrical. This symmetry, in my opinion, depended on the equal exposure of the affected areas to the sun's rays. If the exposure were greater for one limb there would be a correspondingly greater extent of eruption on that side. I am quite satisfied that the distribution of the rash was directly proportional to the time and the extent of the exposure. For instance, in a rash on the chest—an uncommon site—the outline corresponded to the opening of the shirt. In the case of Turks, the rash on the feet was limited most accurately by the edges of the slippers worn. I have noticed that sun exposure intensified the eruption and that if the patient exposed himself too soon after the subsidence of an attack there was a great tendency to recurrence.

Aberrant types of the rash, in which there was diffuse generalised pigmentation and desquamation, have been observed. The occurrence of petechiæ in the eruptive areas denoted a much more severe attack, although it must be distinctly understood that, except for the rare form of the disease known as pellagra typhus, of which I have seen only two cases, the wet form must be regarded as the most serious.

Pellagra *sine* pellagra, or pellagra without a rash, is of doubtful occurrence, and accordingly needs no comment.

The differential diagnosis of the rash from allied skin affections offers no formidable difficulties to the experienced observer. The principal diseases simulating it are ordinary sunburn, eczema (erythematous form), lupus erythematosus,

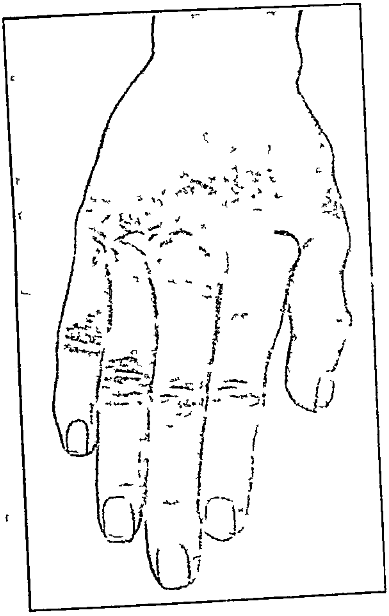

FIG 1—Eruption on hand illustrating the pigmented cuticle which is desquamating, and also the fissuring around the knuckles

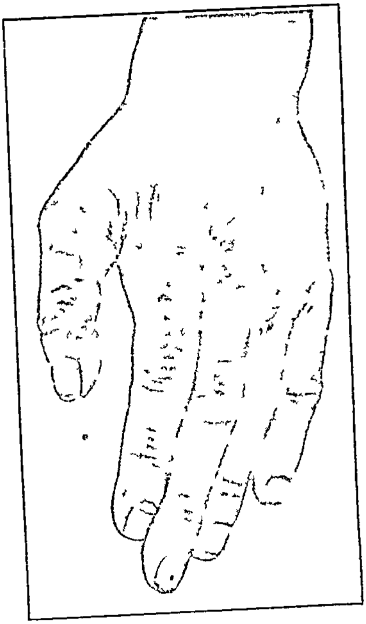

FIG 2—An earlier stage showing the complete pigmentation of the back of the hand Desquamation is just commencing There is also fissuring of the skin over thumb

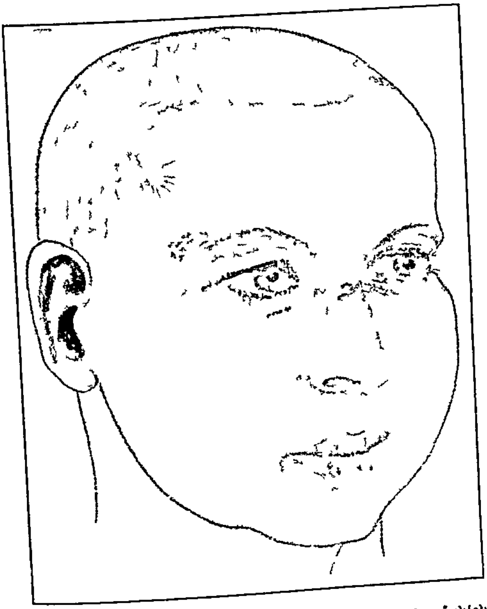

FIG 3—Showing the typical distribution of the rash on face which is swollen Note the pigmented area on nose and in front of the ear, the cracked lips and the septic spots in right anterior temporal region The painting reproduced was done within 24 hours of the onset of the œdema, which was of a transitory character

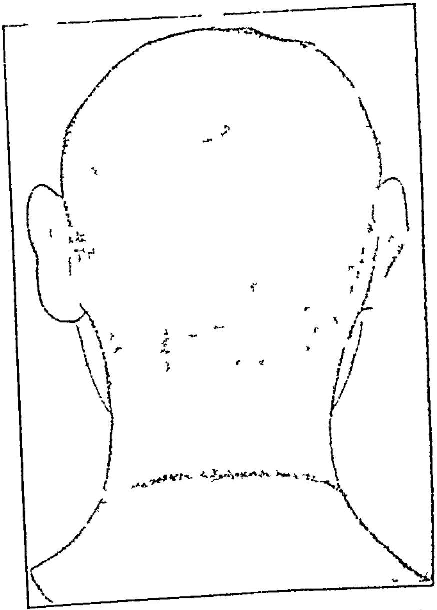

FIG 4—Showing the eruption on back of neck Desquamation is almost complete and the dark lines represent the last vestiges of pigmentation Note the collar-like appearance of the rash

College

and erythema multiforme. For a detailed account of the differential diagnosis the reader is referred to Swanson's excellent monograph.

The average duration of the rash was about three weeks.

In the eruptive stage the epithelium of the tongue exfoliated and left the tip and edges, in which the fungiform papillæ stood out prominently, bright and shining. In this way the characteristic "stippled" tongue, which must not be confused with the sprue tongue, became noticeable. The mouth was sore and sensitive; the buccal mucous membrane was congested and sometimes showed scattered vesicles. White aphthous patches were occasionally seen, especially on the under and anterior surface of the tongue. The whole organ became enlarged and fissured. The tip and edges were usually inflamed, more rarely pale and anæmic.

General Symptoms and Physical Signs.

In the eruptive stage the patient was very weak and frequently compelled to remain in bed. The facies presented a drawn anxious appearance, there was considerable muscular wasting, the appetite was poor, and a subacute diarrhœa persisted. There was great mental depression amounting almost to melancholia. If the case was more severe, dysentery, either bacillary or amœbic, usually supervened and the wasting became accentuated. The majority of these German cases, however, were comparatively mild, and though at first losing weight they steadily improved after the disappearance of the rash. The subjective sensations experienced by the patient in the stage of onset continued throughout this stage.

A peculiar afebrile *parotitis* was relatively common among these Germans. In some both parotids became enlarged and, after an interval of about 14 days, subsided, whilst in others they suppurated and discharged much pus, from which a staphylococcus was isolated. The exact cause of the parotid enlargement is not definitely known. Some six months previously I had seen a similar outbreak of parotitis among otherwise healthy Turks. The temperature was normal, and orchitis was not observed. The parotids were swollen, but, unlike the German pellagra cases, showed no tendency to suppuration. In these Turks the only explanation suggested was that an infection of Stenson's ducts from pyorrhœa had taken place. However, though I could not give exact reasons for my opinion, I then thought that the parotid enlargement was due in some way to a food deficiency. When this same parotitis occurred afterwards in German pellagrins I was still more convinced of my former opinion. The presence of thrush-like patches in the mouths of some of these same cases may also be significant. Many of them also had diffuse septic sores on the face and hands, while they complained of great thinning of the hair in the temporal areas.

Nervous system.—The knee-jerks were often sluggish and occasionally absent. The cornea and pharynx of some were insensitive. Otherwise there were no evidences of nervous derangement. Mental symptoms were not observed.

Œdema.—A transitory œdema of the face, feet, or hands occurred in many cases (see Table II.). Sometimes it disappeared in 24 hours (see figures); in other cases it persisted as long as 14 days. The œdema invariably disappeared when appropriate treatment was applied. It was not as extensive or resistant as the œdema occurring in the Turkish cases.

Blood.—(*a*) The blood pressure was lowered; average systolic pressure 90, diastolic 80 (Table II.). (*b*) The total red cell count deviated only slightly from the normal, showing a secondary anæmia. No alteration in the size and shape of the red cells was detected. Neither was there any characteristic change in the total number of white cells. There was a slight relative increase of lymphocytes, but they were not markedly in excess, as in many of the Turkish patients. The mononuclears were above the normal in cases complicated with malaria. No eosinophilia was observed. (Table II.)

Urine.—Except for the presence of indican (Table II.) the urine was almost invariably normal. A trace of albumin was only very occasionally present. The significance of indican in the urine of pellagrins, though important as denoting lack of gastric function, is apt to be exaggerated, as Hunter, Givens, and Lewis have shown that pellagra may exist without formation of this substance. The amount of indican in the urine varies inversely with the acidity of the gastric juice and, if excessive in amount, is an index of abnormal protein decomposition.

Tr. = trace; + = pure Fehling; D & M = dysentery and malaria; Pr. = previous; bl. = blood; mu. = mucus.

Stools.—Only three cases had normal stools. Otherwise diarrhœa was a characteristic feature. Judging from the offensive odour of the copious—sometimes porridgy—evacuations, unusual bacterial putrefaction had taken place. The presence of undigested muscle and vegetable fibres emphasised the defective gastric secretion and corroborated the indicanuria already noted. The diarrhœa often became dysenteric in character. The organisms in the stools were either *Entamœba histolytica* or the dysentery bacilli, more frequently the former. No abnormal organism, which could be proved to have any specific relationship with pellagra, was discovered. It may be mentioned that *Ascaris lumbricoides* was often present.

Lungs.—Usually normal. Only one case of pulmonary tuberculosis was diagnosed.

Heart.—Functional hæmic bruits were occasionally heard. Otherwise no abnormality in the size or sounds was detected.

Liver.—Normal in all cases.

Spleen.—Frequently enlarged, indicating a previous malarial infection.

Prognosis.—As all these cases were primary attacks, the prognosis was, on the whole, good. When my observations concluded 31 had been discharged as apparently quite fit; while of those still remaining in the hospital 22 were decidedly improved, 6 were in statu quo, 4 were worse than on admission, and 2 were in a critical condition. Only one patient had succumbed. The increase in weight (see Table I.) recorded in the majority of the cases augured well for their eventual recovery.

Treatment.

The first essential in these cases was the effective treatment of any coincident disease. If the patient had dysentery, serum or emetine (intramuscularly) in combination with sodium sulphate by the mouth was administered, and a milk diet, sometimes with the addition of chicken and two eggs, was prescribed. Malaria, which was very common, was treated by a course of intramuscular quinine, followed by a mixture containing quinine, iron, and arsenic.

When the superadded infection was thus treated and relieved the treatment of the pellagra itself was undertaken. It consisted of rest and an increased dietary. The hospital full diet—recorded in an earlier part of this article—augmented by 7 oz. of meat, 7 oz. of bread, and two eggs daily, was given, and the patient was ordered to remain indoors and at rest. If the stools continued solid he became gradually better. His general health improved, he increased in weight, and the rash slowly disappeared. As long as diarrhœa did not occur the prognosis was good. Eventually he became robust and expressed himself as feeling very well. Whether the pellagra was permanently cured or not it is as yet impossible to say, as there might be a recurrence of the disease in the following year. It would be interesting to know how many of these cases relapsed during the spring of 1920.

Persistence of the diarrhœa was regarded as of grave import. It interfered seriously with the patient's prospects of recovery and was an indication of his defective assimilative powers. Diarrhœa and wasting were invariable symptoms in those doing badly. However, the immediate effects of this dietary were extremely satisfactory, as evidenced by the fact that 46·1 per cent. were discharged as apparently cured and 33·8 per cent. were decidedly improved, even though not fit to be discharged from the hospital.

Conclusions.

In view of the findings resulting from the investigation of this outbreak, the "food deficiency theory," which has been considered on apparently adequate grounds to be the cause of pellagra, is seriously threatened. I do not mean to suggest that a food deficiency can be quite excluded, but from the facts before us it can hardly be considered as of paramount importance. Obviously something more than a dietetic factor is involved.

A critical analysis of the diets which these German pellagrins ate before capture and during their period of captivity prior to the onset of the eruption is sufficient to explode the food-deficiency theory as a predisposing factor. These diets were ample, both in quantity and quality, for any possible requirements, and were of such varied composition that it is perplexing to understand how they could have been improved.

If the account of the diets is accepted as accurate—and I firmly believe it is accurate—the causation of the disease, far from being elucidated, becomes still more obscure. Thus it is necessary to seek some other explanation.

Let us consider how the beneficial effects of a diet sufficient for a normal healthy individual, doing a normal amount of work, are liable to be counteracted. An originally good diet may be vitiated by loss through (1) abnormal expenditure of energy, (2) defective assimilation, consequent on impaired digestive function, (3) absence of some internal secretion which is necessary for protein metabolism.

To what extent, if any, was the German diet affected by the above factors? Firstly, I do not think the Germans were subjected to undue hardship or did excessive work on the Palestine front. Many of them were employed on the lines of communication, where there was neither strenuous labour nor scarcity of food. We know that the Germans attached to the Turkish forces were picked men, who supervised affairs, and were not called upon to over-exert themselves manually; they left the actual physical labour to the Turks.

That the pellagrins suffered from defective digestive assimilation is undoubted. The incidence of malaria and dysentery was very high, and was responsible for intestinal derangement, which was a marked feature of the majority of my cases. Judging from the indicanuria commonly present and the copious foul-smelling evacuations which frequently contained undigested food material, it is evident that there was abnormal protein decomposition, and that the ultimate good effects of the diet were largely vitiated or entirely lost in this manner.

Hence, a second factor, such as previous disease, must have been in operation. Is this, however, a satisfactory explanation? Though possibly a contributory cause, a previous disease could not be held directly responsible. Otherwise, how does one account for the absence of pellagra amongst British troops who had been affected in an almost equal degree with malaria and dysentery? Again, how does one account for the absence of pellagra from the diseased and poverty-stricken masses of pe during the same period?

Lastly, are there any reasons for thinking that an internal secretion may be implicated? It has been suggested that adrenal insufficiency was the immediate cause of war œdema, which is, in my opinion, closely related to the œdema of pellagra. The probability of a hypoadrenalinæmia in war œdema is, however, based on a previous food deficiency. As we do not admit a deficiency of accessory food-factors in this outbreak, neither the information gained from the study of war œdema nor the recent researches of McCarrison are applicable and, consequently, are of little assistance in elucidating the causation of the disease among the Germans.

There was certainly no lack of fresh fruit in Palestine and Syria during the enemy occupation, as the entire orange crop of Jaffa and surrounding districts was at their disposal. One might suppose, when one considers the great improvement made by the majority of the cases on the augmented hospital diet, as prescribed in the treatment, that the former diet was defective. To obviate such a misapprehension let me direct attention to the German camp diet at Maadi prison camp, and the excellent testimonial given it by the members of the Pellagra Commission inquiry. Yet two Germans, who spent a year in that same camp on that same diet, developed the disease. I quote this example to prove that the record of the diet in Palestine is probably accurate, and that it also was satisfactory in every respect.

I have already referred to the occurrence of a parotitis and its probable significance. It would be interesting to know whether the parotid enlargement was due merely to secondary infection from the mouth or to some other and as yet unknown factor. Does the parotid possess any rôle in protein metabolism? I realise that I am treading on thin ice when I hazard the suggestion that this gland may possess an internal secretion, the function of which is concerned in the economy of protein, just in the same manner as the pancreatic secretion is essential for normal carbohydrate metabolism. I am not aware if complete extirpation of the parotids has ever been attempted. It would be of interest to discover what changes would result from such an operation.

I may add that Major P. J. Smyth, R.A.M.C., had observed a similar parotitis in Salonika. He, too, was at a loss to understand its causation, but was of the opinion that it might be due to a dietetic disturbance. The association of the parotitis with pellagra is curious and may have some relationship to the production of the latter.

Although I have been unable to advance any satisfactory cause for this most mysterious outbreak of pellagra, I do submit that I have established a clear case against a "food deficiency" as being the only factor involved.

In conclusion, I wish to record my indebtedness to Dr. Manson-Bahr for his valuable assistance, both in supplying me with information and in making suggestions for this paper. I must also thank Colonel P. S. Vickerman, R.A.M.C., for the facilities he afforded me in investigating these cases and Captain R. Paton, R.A.M.C., for the blood counts which accompany this article.

SYPHILIS IN DISEASES OF THE HEART AND CIRCULATION.

BY CHARLES W. CHAPMAN, M.D. DURH.,
M.R.C.P. LOND.,
CONSULTING PHYSICIAN TO THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART.

THERE are reasons for expecting visceral manifestations of syphilis to appear at an unusually early period in the case of those who have gone through the stress and strain of the late war. Cases of atheroma and tabes occurring thus early have already been reported, and it is fair to assume that the heart and other internal organs are equally prone to premature degenerative changes.

The cardio-vascular system does not escape injury in congenital syphilis. The late George Carpenter read an exhaustive paper on this subject,[1] which will repay careful study. An apposite case was contributed by the present writer.[2]

The case was that of a girl, aged 15 years, whose mother had a strong history of syphilitic infection. The patient had had the usual symptoms of congenital syphilis in infancy and presented the characteristic facies of the disease. She had palpitation and marked dyspnœa. The cardiac dullness was increased, with heaving impulse, induration of the larger arteries, and the liver was enlarged nearly to the umbilicus. No murmur was found, but the aortic second sound was accentuated. The urine contained 2½ per cent. of albumin, and there were tube casts; pulse rapid and of "tick-tack" character. After a temporary improvement the child died of heart failure. There was no history of rheumatic or any other infection. At the post-mortem the cavities of the heart were found dilated and the left ventricle hypertrophied. No valve lesion was found.

In regard to the effects of acquired syphilis on the cardio-vascular system in the adult, in a recent work by the late Dr. Edward Lea[3] reference is made to the writings of Ambrose Paré (1510–1590), in which he comments on the relationship of aneurysm to syphilis, an idea which was developed by Landsici (1727). On p. 193 et seq. Dr. Lea speaks in no measured terms of the potency of the syphilitic factor in relation to circulatory disease.

> "The virus of syphilis is the arch enemy of the circulatory system; it is the main cause of aortic regurgitation, also of aneurysm; it rots the blood-vessels, leading to hæmorrhages ofttimes fatal. It blocks the smaller arteries—arteritis obliterans. The severest and most painful forms of aortic inflammations are due to syphilis. Clinical heart-block is usually formed by a gumma. Yet we are only at the beginning of the influences and potentialities for harm. ...... To cardiology will be added a useful chapter when the ultimate clinical effects of syphilis upon the heart have been more fully investigated."

Osler,[4] on syphilis of the heart, remarks, "A fresh warty endocarditis due to syphilis is not recognised, though occasionally in persons dead of the disease this form is present." The author quotes Janeway, Loomis, and others on the presence of gummata, fibroid and amyloid degeneration of the heart.

In annual Reviews of the Literature of Heart Disease in the *Practitioner*, I have frequently referred to contributions from various parts of the world bearing on this subject. Thus, in the number for June, 1914, a paper by Warthin is summarised as follows:—

> "Syphilis is more productive of heart disease than is generally supposed, and that it is frequently associated with syphilitic affections of nerve, brain, bone, and aorta. The author states he has had 200 syphilitic hearts, 50 congenital, 150 acquired, at all stages; he considers that primary lesions may be parenchymatous or interstitial. ...... The author concludes that syphilis, both congenital and acquired, is the most important factor in myocardial and endocardial diseases."

In the same review is given a case of complete A-V heart-block, in which there was a definite history of syphilis and a positive Wassermann present.[5] Lauder Brunton[6] describes a case of angina pectoris in a syphilitic subject who contracted the disease 12 years previously. The author attributed the angina to reflex irritation from a node over the sternum or possibly to the involvement of some of the cardiac nerves. Iodide of potassium completely cured him. Clifford Allbutt in his classical work,[7] vol. ii., p. 145, thus graphically describes the after-effects of aortitis.

> "The aorta of a man 55 years of age, who has taken freely of drink and suffered from syphilis, lies before us. The vessel (aorta) is heavy, baggy, and hard; its walls are beset with knotty masses. On laying it open we find the stretching has told chiefly upon the ascending arch and vault, and that besides the old syphilitic pouches and scars, and engrafted upon them, atheromatous bosses and plates, some calcareous, some ulcerated, now occupy its inner face. The aortic cusps are thickened and deformed; the sinuses of Valsalva are contracted, and the orifice of the heart is altered. The orifices of the coronary arteries also are invaded by atheroma; the orifice of the right coronary artery occluded perhaps, so that of the left barely admitting a bristle. The cusps, altered as they are, may be competent against regurgitation; the heart in substance looks healthy, and to the naked eye and the microscope, looks healthy, in spite of the interference with the mouths of the coronary arteries, presents in its muscular tissue no worse sign of degeneration than a moderate fibrosis."

On p. 239 the author writes:—

> "The cases I have seen (of angina) in younger persons have all originated in the specific infections—especially in syphilis, rheumatic fever, and influenza."

It is not safe to place implicit confidence in the patient's denial of having had syphilis when clinical evidence points the other way, neither is a negative Wassermann always to be trusted. In the present writer's experience tactful inquiry will often confirm a strong suspicion. In women a history of several miscarriages is strong evidence in favour of syphilis. A case was seen on the day of writing this paper where, in addition to miscarriages, all the children born alive had sore buttocks and were treated with mercury by the late Jonathan Hutchinson.

Illustrative Cases.

CASE 1.—H. A., 50, married, consulted me in 1902; one son and one daughter, the former healthy, the latter an epileptic. No family history of fits. History: Syphilis

in India at 19, malaria in W. Indies at 25. Took alcohol rather freely when young, now takes four "drops" a day. Complains of pain in the cardiac region, palpitation, and shortness of breath on any exertion. He has been worse lately, and can only walk a few yards; occasional giddiness, also much flatulence. Examination: Tongue red, stomach dilated, liver down two fingers, cardiac dullness just outside nipple line; apex beat sixth space, rough systolic murmur at mid sternum; arteries thickened, hard and tortuous; deficient resonance base of left lung due to old pleurisy; urine normal. Has lost flesh, teeth bad, pulse 76. As the stomach symptoms were the most urgent treatment was directed to their relief. A fortnight's rest was ordered, after which period antisyphilitic treatment was commenced. After a few weeks the patient lost weight and it was feared tuberculosis had set in, but no tubercle bacilli were found, and later on he put on weight and lost all the cardiac symptoms. I saw the patient at long intervals, and he held his ground well. On June 28th, 1913, he came up on account of soreness of the mouth, especially at the angles; these sores were characteristically specific, there was, moreover, a large gumma on the left side of the tongue. Green iodide of mercury was prescribed in conjunction with local treatment, and ultimately the mouth was well. There had been no visible sign of syphilis for 30 years. The patient is in better health than 18 years ago.

CASE 2.—T. G., 54, *married, one child, consulted me* in December, 1915. He complained of pain in the left wrist, running up the arm and radiating across the chest, provoked by walking or any exertion and relieved by stopping still and eructation. History: Rheumatic fever at 5 years; syphilis at 20, passed several small renal calculi at 32, influenza at 51. Present symptoms commenced a year ago while ascending a hill, increasingly worse the last three months in spite of treatment. Examination: Patient looks ill and has an anxious expression. There was dullness and hyperalgesia over the upper two-thirds of sternum, extending ¾ inch to the left, apex beat sixth space nipple line, heart dullness extended to left nipple line and to right *side of sternum. A double murmur in aortic area, the* diastolic being loud and blowing, a feeble systolic murmur at the apex increased on lying down, pulse 84, moderately splashing, arteries hard and tortuous and visibly pulsating, blood pressure 220/70, Raynaud's symptom both hands. Other organs apparently healthy. The patient was ordered to take one month's rest in bed, light nutritious diet, light wine in the place of whisky, and antisyphilitic treatment with small doses of tr. digitalis was prescribed, and a trinitrine mixture with ether for pain. The treatment had to be varied from time to time. By the end of the month the patient was able to walk a short distance without pain. Improvement was steadily maintained so that by the end of June he could walk half a mile without pain or inconvenience, and a few months later he was able to dig and mow grass. He was last seen in 1919, when the sternal dullness and hyperalgesia were gone, the murmurs were as before.

It was impossible to say which of the three infections was most responsible for the cardio-vascular lesions, but aortic disease does not commonly follow rheumatic fever, especially so early in childhood. Again, a year elapsed from the influenza without heart symptoms, so the presumption was in favour of syphilis.

CASE 3.—A. W. consulted me at long intervals on account of bronchial catarrh and indigestion. The breath was short on much exertion, but this could be accounted for by emphysema. The chest was thoroughly examined from time to time without anything abnormal about the heart being discovered. Eighteen months ago I saw him in bed for the first time when, in addition to bronchitis, I found extension of the heart dullness increased in both directions and a systolic murmur at the apex. I thought the heart would improve as the bronchitis cleared up, but the murmur remained. In December, 1919, he was again very ill from heart failure and dropsy. As the patient could not be efficiently nursed at home he was removed to the Middlesex Hospital. Later on I called to see him, when Dr. Voelker, under whose care he was, called my attention to some scars on the soft palate and damage to the uvula. These, owing to my attention never having been called to the mouth or throat, had escaped my observation.

The lesson to be learnt is that when a patient with organic heart disease comes before us and there is no history of the more usual infections syphilis should be suspected and confirmatory evidence diligently sought for, especially in patients at or after middle life. When the cardiac symptoms are not urgent it is advisable to prescribe a period of rest, together with a short mercurial course, before proceeding to the administration of the more direct cardiac remedies.

NOTES ON THE
CAUSATION OF RED DEGENERATION.*

BY R. H. PARAMORE, M.D. LOND., F.R.C.S. ENG.,
SURGEON TO THE HOSPITAL OF ST. CROSS, RUGBY

THE specimen of a uterus shown in the illustration, the seat of a fibroid which had undergone "red degeneration," was obtained from a single woman, 27 years of age, who was admitted to this hospital on June 2nd, 1917, under my care. She was thought to have appendicitis. The illness began on May 25th, when during a railway journey she felt a sharp cutting pain, soon passing off, on the right side of the abdomen. Reaching home at 6.40 P.M., she avoided supper (as she often did) and went to bed in her usual health. At midnight she was awakened with severe pain in the lower part of the abdomen, vomited, had diarrhœa, and fainted. Later she fell asleep till 6 in the morning. On rising she felt giddy and still had pain, but in spite of it, went her round delivering letters on a bicycle for an hour. She spent the next two days on a couch with light food, but the pain persisted. On May 31st she was advised to go to bed, but on this day her period began, and the pain in the abdomen ceased. Her temperature, however, was still raised and the bowels confined. On June 2nd, the temperature continuing, she was sent into hospital with the diagnosis of appendicitis.

On examination, the patient was not anæmic, and looked fairly well. Her temperature was 100°F., and her pulse 96. Her tongue was not clean; she had not been sick since the onset of the illness, but the bowels had been opened just before admission, the result of medicine (compound liquorice powder) two nights before. The abdomen was not distended and moved easily on respiration. There was no rigidity. There was no lump to be felt in the region of the appendix, deep palpation at McBurney's point caused no pain. On palpation of the hypogastrium, a resistance was felt rising 2 inches from the superior border of the symphysis. Pressure in this region was not painful; at most a little tenderness was complained of low down on the right side. Here, a small movable lump, evidently a gland in the lower abdominal wall, above Poupart's ligament was felt, and at times was painful.

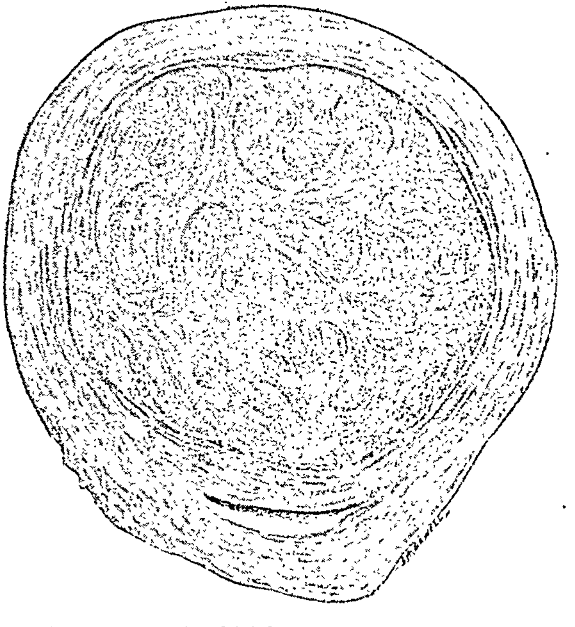
Inspection of the vulva revealed nothing in particular—the hymen had been dilated. Per vaginam, the cervix was normal and nulliparous. On bimanual examination, the pelvic cavity was found occupied by a tumour, the size and shape of a large orange, of a smooth and regular surface, hard to the touch, easily movable within limits in all directions, as though its volume alone restricted its displacement. The tumour was continuous with the cervix. The breasts were inactive. A diagnosis of uterine fibroid was made. The menstrual history confirmed this opinion. During the last six months the periods had increased in duration; instead of four days they have lasted five or six or even seven days, and the intervals between them have diminished. The loss has gradually become much greater, so that whilst formerly five or six diapers sufficed, latterly she has had to use 16 or 17. The pain, which has preceded the periods since her eighteenth year, has also increased. She began to menstruate when 13 years of age.

Differential diagnosis.—The question now arose whether the fibroid or some other pathological condition was the cause of the signs and symptoms of the disease. We had no knowledge as to the size of the uterus before this attack. Examination of the abdomen, however, was negative as to the presence of any other pathological condition, and nothing abnormal was found in the head, neck, chest, or limbs. The urine was normal. As the patient was menstruating, the question of a uterine discharge could not be cleared up, although she gave no history of one. An inflammatory state of the fibroid, due to a possible infection, seemed unlikely. The tumour was hardly large enough to support the idea of necrosis due to a slowly occurring deficient blood-supply, and the acute onset was opposed to this, whilst red degeneration was dismissed because the cause of the red degeneration, as I saw it, did not exist. The patient was not pregnant, and there was no evidence that the pressure conditions within the abdomen were abnormal. As there was no obvious reason for operating immediately, I decided to await events.

---

* Read at a clinical meeting held at the Hospital of St. Cross, Rugby, Feb. 28th, 1920.

Course.—With rest in bed and dieting, and attention to the bowels, the patient's condition gradually improved. The temperature slowly fell and the pulse with it. No sign of inflammation of the appendix showed itself.



Specimen of a fibroid which has undergone red degeneration removed from a single woman.

On June 7th the menstrual flow ceased, having lasted eight days; there was no subsequent vaginal discharge, and nothing abnormal was found in the cervix or vagina. I decided to operate as soon as the patient's temperature became normal. This happened on June 13th, and the next day I removed the uterus, leaving the cervix.

At the operation, from which the patient made an uninterrupted recovery, the tumour was found to occupy nearly the whole of the pelvic cavity, so that difficulty was experienced in drawing it up. It looked exactly like a pregnant uterus, was quite symmetrical, but instead of being cystic was hard. After removal it was hardened in formalin, and on section in the antero-posterior plane revealed a single intramural fibroid of the colour of raw meat.

Pathological Report.

The fibroid occupied the centre of the enlarged uterus and was everywhere surrounded by uterine wall which was fairly thick. It had grown from within one or other of the uterine walls, and had displaced the uterine cavity. Its discolouration was uniform, and markedly contrasted the diseased part from the healthy musculature of the organ, which was of its usual white colour. A portion of the uterine wall and of the tumour was sent to the University of Birmingham for histological examination. Professor Leith kindly examined it. In answer to my inquiry whether the uterine musculature was hypertrophied, Professor Leith wrote: "There is every appearance to the naked eye of hypertrophy of the uterus here, as there is in most other fibroids ......" And, as to the cause of red degeneration, he said: "The chief points about red degeneration are: (1) the asserted thrombosis and its cause; and (2) the undoubted hæmolysis and its cause." In his report on the sections, he says: "In the outer part of the fibroid (are) large blood-vessels, but they are not thrombosed, nor is there any obvious thrombosis throughout the whole series of sections, so far as I can see." The outer part of the fibroid also "shows degeneration but no actual necrosis." Sections from the inner parts of the fibroid, however, do not show "much degeneration. In great part they are histologically sound. ...... There is no thrombosis, no excess of fat, and very little, if any, necrosis, only a patchy degeneration." He ends by saying that most of the red degenerations he has examined "have shown imperfect necrosis and unsatisfactory evidence of degeneration compared with the degree of naked-eye change which they exhibited."

Pregnancy an Exciting Cause of Red Degeneration.

The red degeneration of fibroids is rather interesting. It is much more common in pregnant than in non-pregnant women. It causes a toxæmia (as shown by its effect on the temperature and pulse); it causes pain; and it causes an enlargement of the tumour. Pregnancy is a powerful exciting cause (Bland-Sutton).[1]

Out of 40 specimens Bland-Sutton examined, 26 were associated with pregnancy. But I scarcely think that 14 out of every 40 of these cases come from non-pregnant women. Kelly and Cullen, in their work on myomata of the uterus, a study confined for the most part to the non-pregnant, seem scarcely to have met the condition.[2] The toxæmia has been attributed to an infection by pyogenic organisms (staphylococcus). But Lorrain Smith and Shaw, who out of four cases found this organism in two, conclude "that the bacterial infection is secondary to the occurrence of the thrombosis."[3] Bland-Sutton is also of the opinion "that microbic infection of red fibroids is a sequence and not a cause of the change," and that "micro-organisms are rarely found in red fibroids."[1] He believes the condition is due "to mechanical interference with the circulation."[4]

Whether a toxæmia—using that word in its widest sense—is present in all cases of red degeneration I cannot say. Everybody seems agreed that the tumours become enlarged and tender. "Fever," says Bland-Sutton, "is not a common symptom, but it occurs." The patients, however, as is plain from reported cases, often become profoundly ill. "When a pregnant woman complains of acute pelvic pain," says Bland-Sutton, "and the presence of a uterine fibroid is unsuspected, then grave errors of diagnosis happen and occasionally unnecessary operations are performed." I suggest that when fever is not observed it is not looked for, or only a slight rise of temperature is found. In my case the highest temperature recorded whilst the patient was in hospital was 100·6°. The fever, apparently, is usually slight, comparable with the fever observed after many operations, due to the absorption of blood or its products, and aseptic in type. But that this is a toxæmia cannot be gainsaid. It is a mild toxæmia, but still a toxæmia. The presence of micro-organisms is adventitious; the toxæmia I refer to is not due to them; they occasionally complicate the condition which it is desirable to contemplate in its purest form.

The cause of this change is interesting. What we have to explain is the swelling; the dilatation of blood-vessels; the diffusion and hæmolysis of blood. I believe Bland-Sutton is right—that the change is due to a mechanical interference with the circulation. Such an interference may arise in two ways: (1) It may occur as the result of persistent and spasmodic contraction of the uterine musculature enclosing a fibroid, or (2) it may occur through general increase of pressure in the abdomen, as in pregnant women.

Rhythmic variation in the contraction of the uterine musculature is presumably a normal occurrence; in the pregnant uterus such variations can be observed. In the non-pregnant increase in contraction is a prelude to normal menstruation, the contraction becoming sufficient to interfere with the nutrition of the endometrium, which swells, partly necroses, and is shed mixed with blood.

[3] Pathology of Red Degeneration of Uterine Myomata, Jour. Obstet. and Gyn. Brit. Emp., April, 1909, p. 225.

[4] Red Degeneration of Uterine Fibroid, Proc. Roy. Soc. Med., Obstet. and Gyn. Sect., 1909, p. 301.

In dysmenorrhœa the contraction is so great as to cause pain, and this pain is persistent, perhaps for a day or two, indicating the persistence of the contraction, and this pain, as we know, is experienced before the flow. With the cessation of the pain and the diminution of the contraction the blood escapes from the dilated broken vessels. Thus the idea that the uterine musculature, in virtue of an increased contraction, may be associated with a vascular change of magnitude in fibroids it surrounds is supported by analogy. And that such a factor was in play in my case is supported by the position of the tumour and by the hypertrophy of the uterine walls embracing it.

Increase of Pressure as a Causal Factor.

But another factor seems to be necessary, otherwise red degeneration would be much more common than it is. Such a factor may be a preliminary engorgement of the tumour, induced by trauma or by jolts, due to rises of pressure in the abdomen itself. Such jolts may perhaps act directly on the uterus, causing its musculature to contract more markedly than usual. The jolting sustained by my patient on her train journey may have played such a part. The tumour becoming enlarged by vascular turgescence puts the uterine musculature surrounding it on the stretch, and this in turn induces a contraction, or a further contraction of the uterine musculature, intense enough to interfere with the blood supply to the tumour. In support of this we have the enlargement of the tumour and the pain induced. In my patient we noticed the pain complained of immediately disappeared when the menstrual flow began, because, presumably, the uterine musculature relaxed. Even in subserous fibroids which have become swollen from this change a relaxation of the uterine musculature, by allowing a return flow from the tumour, may affect the pain and tenderness experienced. To such an argument it may be opposed that the uterine musculature itself remains healthy; if it causes a necrosis of a contained tumour, why does it itself not suffer? A ready answer is that the uterine musculature is a normal tissue, and its nutrition is more regulated than that of pathological parts; but whether this answer will satisfy critics remains to be seen.

That increase of pressure is a causal factor in the red degeneration of fibroids is indicated by the much more frequent occurrence of the change in the pregnant state. The intra-abdominal pressure, as I have shown, is raised in pregnancy,[6] and this increase influences the blood flow through all the abdominal organs. The arterial pressure is raised, but the capillaries are more compressed. The venous return, at least from some parts, is impeded, as shown, for example, by the bluish discoloration of the vagina. But even here jolts and jars or activity appear necessary. Most interesting is it to find that one of Bland Sutton's patients had an experience similar to mine; she was seized with the pain whilst on a train journey. She was a primigravida, aged 30, two months pregnant, who had been to London to consult a doctor. This doctor expressed himself as satisfied with her condition. Whilst on her return she was seized with such sudden and acute pain that she left the train at an intermediate station and placed herself under the care of a doctor she knew. A large tender swelling was discovered on the right side of the abdomen and thought to be due to a ruptured tubal pregnancy. The next day Bland Sutton "found a large tumour, probably a fibroid, occupying the right half of the belly, and reaching as high as the liver." The pulse was 112 and the temperature 100°. The tumour was a large subserous fibroid, with a broad stalk. It presented an area of softening, about 5 cm. in diameter. This patch appeared acutely inflamed, and was covered with flakes of lymph. Deep to it the tumour was the seat of a red degeneration. Other fibroids were present in the gravid uterine wall and exhibited the red change in streaks.[4]

Jolts and jars must necessarily cause considerable variations in the intra-abdominal pressure; to meet them the tonic contraction of the body-wall musculature is increased, so that the average pressure is raised. They may perhaps act by causing a kinking of the veins in pedunculated fibroids, or, if they stimulate the uterine musculature to contract, this contraction may obstruct the return of blood from such parts. Such an interference must cause a turgescence, a dilatation of the vessels, and a swelling of the tumour; the further obstruction and compression of the tumour, in the presence of a raised arterial pressure, causes a rupture of capillaries, an effusion of blood, a more marked swelling, and the pain. The blood rapidly hæmolyses and pigments the tissues, whilst its products entering the blood stream cause that elevation of the temperature and rapidity of the pulse with which we are familiar. When such fibroids are left the toxæmia subsides, as my case shows. The fibroids themselves may become diffluent, converted into cysts with chocolate-coloured contents (Bland Sutton). When subserous they become adherent to surrounding parts—to the abdominal wall and intestines, which may mask their nature and render removal difficult (Lorrain Smith and Shaw). When intramural it is possible calcareous salts may be deposited and the tumours in time be discharged as "womb stones."

Analogy with a Twisted Pedicle.

That the red degeneration of fibroids is really caused in this way is, I think, also shown by what happens when the pedicle of an ovarian cyst becomes twisted. There is a marked similarity between the signs and symptoms of red degeneration of fibroids and those resulting from the latter accident. The onset of the pain is alike acute, the patient may vomit, and the temperature is raised and the pulse increased. Such a case was sent into hospital on May 30th of last year labelled pyosalpinx. The patient presented all the appearances of an acute abdominal condition. A lump was felt in the left iliac fossa, which was painful and tender. The overlying abdominal wall was rigid, and the bowels were confined. The temperature was 101.4° and the pulse 120. On opening the abdomen, which was done next day, an ovarian cyst the size of a child's head, swollen, congested, suffused with blood, with a thick, œdematous, hæmorrhagic, and twisted pedicle, was found and removed, recovery being uneventful.

I instance this case from the toxæmic point of view. Like that of the red fibroid, this case presented the characteristics of a toxæmia, masked, however, by the local changes. But here there is no question of a preliminary thrombosis of contained vessels, nor are pathologists worried by the cause of the hæmolysis. The toxæmia is slight and traumatic, the same as results from the red degeneration of fibroids. These tumours when left, like red fibroids, become adherent to neighbouring parts, the toxæmia subsiding. Illustrative of this is a case admitted on Dec. 27th, 1918. The patient was 76 years old. The history was that 14 days before she had had an attack of pain and vomiting. There had been no previous attack. On admission the temperature and pulse were normal. On opening the abdomen a fairly large cyst, the size of a coconut, was found with a twisted pedicle. It was adherent to omentum, but presented no sign of acute strangulation. Recovery was uneventful. I had a similar case whilst on military service at Grantham. A woman was admitted with ill-defined symptoms. A diagnosis was not made. The abdomen was opened; a flaccid ovarian cyst, with degenerate walls, presented. During my manipulations the cyst wall gave way, dirty but inoffensive fluid escaping. The cyst was adherent to the posterior wall of the uterus and was peeled off with difficulty. No complication ensued during the convalescence. It is probable that the cyst had become twisted with a resulting necrosis and consequent adhesion.

THE London (Royal Free Hospital) School of Medicine for Women (University of London) has received a gift of £50 from the Clothworkers Company. A legacy of £200 has also been received from the late Miss Florence Davenport Hill.

ORBITAL HÆMORRHAGE WITH PROPTOSIS

IN EXPERIMENTAL SCURVY.

BY S. S. ZILVA, D.SC. LOND., PH.D. GIESSEN, F.I.C.,
AND
G. F. STILL, M.D. CANTAB., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.
(*From the Biochemical Department, Lister Institute.*)

EXOPHTHALMOS or proptosis as a result of orbital hæmorrhage is an occasional but not frequent concomitant of scurvy in infants. Out of 64 cases[1] 6 showed orbital hæmorrhage, and in 5 of these there was proptosis; the proptosis in all cases was limited to the left eye. Of 11 cases recorded by various observers, 3 showed proptosis in both eyes, 3 in the right eye only, and 5 in the left eye only.

During experiments on monkeys by one of us (S. S. Z.) at the Lister Institute a similar occurrence was recently observed. On March 27th, 1919, the animal, a *Cercocebus fuliginosus*, was put on a scorbutic diet consisting of boiled rice, 250 g.; wheat germ, 50 g.; salts, 2 g.; milk (autoclaved one hour at 120° C.), half a pint daily, with the addition after July 7th of butter, 10 g. On May 21st there was reluctance to use the hind limbs. On the 27th the monkey remained in a lying position and would not sit up. Five c.cm. of unconcentrated decitrated lemon juice[2] were given and repeated the two following days. On the 29th there was some exophthalmos and hæmorrhage in the eyelids. By June 2nd under treatment with the decitrated lemon-juice the eye symptoms had almost disappeared and the legs were being used.

On omitting the lemon-juice the animal again showed hæmorrhage in the eyelids, but with further administration of the lemon-juice the monkey again became quite normal. On July 18th, after discontinuance of the lemon-juice for 29 days, the hind legs were again not used, and the next day purple discoloration of the gums about the lower incisors appeared. There was also some diarrhœa. On the 21st hæmorrhage reappeared in the upper eyelids, and on the 22nd there was marked exophthalmos of the left eye, with such extreme eversion and bulging of the conjunctiva as completely to hide the cornea; the everted conjunctiva was covered with blood. The right eye showed no exophthalmos. The animal was lying on its side unable to sit up, but apparently not in pain. Decitrated lemon-juice of double strength was given in large doses (50 c.cm.) morning and evening, and next day there was much less exophthalmos, though still inability to sit up. On the 24th still larger doses of the decitrated lemon-juice were given, 60 c.cm. of the double strength in the morning and 50 c.cm. of quadruple strength in the evening. The same day the monkey began to move its legs and sat up, and the proptosis of the left eye was greatly diminished, and subsequently disappeared in a few days.

The recovery was extremely rapid; within six hours after the first administration of the double strength decitrated lemon-juice there was a marked improvement in the general aspect of the monkey, although the individual symptoms were still pronounced.

In this particular instance the exophthalmos affected the left eye, in agreement with the special tendency to left-side affection already observed in infants; but further observations will have to show whether this special liability of the left eye holds good in monkeys. Dr. A. Harden and Dr. S. S. Zilva[3] have recorded an experiment on another monkey (*Macacus rhesus*) in which the scorbutic exophthalmos affected the right eye.

◆

A VERY EARLY CASE OF

ILEAL INTUSSUSCEPTION FOLLOWING SEVERE TRAUMA

IN A BOY AGED SIX YEARS.

BY C. M. KENNEDY, M.B.E., F.R.C.S. ENG.,
MAJOR, LATE R.A.M.C. (T.C.); ASSISTANT SURGEON, SOUTH DEVON AND EAST CORNWALL HOSPITAL; LATE ASSISTANT SURGEON, EAST LONDON HOSPITAL FOR CHILDREN.

THE following case is of some interest, because a very early intussusception was discovered 4¼ hours after a street accident. The discovery of an intussusception at a laparotomy undertaken on account of suspected visceral injury in a "run-over" case is certainly unusual.

T. C., a boy aged 6 years, was admitted to the East London Hospital for Children at 6 P.M. on Dec. 4th, 1918. At about 5 P.M. he had been knocked down by a motor lorry. On admission he was quite conscious. Breathing was shallow and difficult. There was bruising of the right hip, right arm, and both knees. There was subcutaneous emphysema of the upper half of the right side of the chest, both in front and behind. The right fourth and fifth ribs were fractured at about their middle. The right base was dull. The abdomen was universally rigid, and did not move with respiration. There were slight fullness and tenderness of the epigastrium, but no tenderness elsewhere. Pulse at 7 P.M., 110. He vomited three times between admission and 9 P.M. Pulse at 9 P.M., 130, feeble, and thready. (The above were the findings of the house surgeon.)

When I first saw the boy (shortly after 9 P.M.), he had already been given morphia. He looked ill. On examining his abdomen I could find no greater rigidity or tenderness than the fractured ribs, with the underlying damage to lung and pleura (as evidenced by the surgical emphysema and dullness at the base) would fully account for. Having regard to this chest injury I was very loth to operate. However, from the bruising it appeared likely that a wheel, or something heavy, had passed over the right side of the abdomen; and might have caused serious damage to the viscera. The rise in pulse-rate between 7 P.M. and 9 P.M. certainly suggested this. The house surgeon who had seen the boy before morphia had been given was confident that there was serious visceral injury. I knew not what signs the morphia might be masking, and therefore reluctantly decided to operate.

The operation was commenced at 9.15 P.M. On opening the abdomen there was no trace of free blood or fluid in the peritoneal cavity. I started on a systematic investigation of the small intestine with no expectation of finding any injury. On reaching about the middle of the ileum I discovered an intussusception little more than an inch in length, with slightly distended gut above it and completely collapsed gut below. This intussusception was easily reduced. No external evidence of injury to the gut either at the site of the intussusception or elsewhere was discovered. After the intussusception had been reduced no marked thickening, such as might have been caused by hæmorrhage into the wall of the gut, could be felt. The abdomen was closed. The wound healed per primam and the patient was discharged apparently well on Dec. 20th.

Remarks.

To me the chief interest in this case centres in its direct evidence that injury may cause intussusception. In the relatively rare cases of intussusception in children over 2 years old (and in adults) trauma may perhaps be a more common cause than is usually supposed. As a dresser I remember having seen an intussusception in a girl aged 7 years, and later as a house surgeon I saw an ileal intussusception in a boy aged 17 years, in both of whom there was a history of a blow on the abdomen. I had been inclined to regard these blows as coincidental rather than causal, even though so well-known a textbook as "Walsham and Spencer" gives trauma among the causes, for patients are very apt to explain any illness as due to some trivial trauma.

I have not attempted to search the voluminous literature on intussusception, but have contented myself with looking up such books and articles on the subject that lay at hand As already stated, Walsham and Spencer[1] mention "external violence" as a cause of intussusception Adams,[2] in a review of 100 cases admitted to St Thomas's Hospital, states that there was a history of injury in only one case Thompson and Miles[3] make no mention of trauma as a cause of intussusception Warren[4] does not mention it Miles,[5] writing in "Choyce's System of Surgery," does not mention it Walton[6] makes no mention of it Souttar[7] quotes Elliot and Corscaden as giving trauma as a definite cause in a few cases

It appears likely that trauma may cause an intussusception in two ways Firstly, it may cause a hæmorrhage into the gut wall, which is then caught and forced onwards in the same way as an adenoma or an inverted Meckel s diverticulum That hæmorrhage into the gut wall may cause an intussusception has been shown by Lett,[8] Sutherland,[9] and Collinson,[10] who reported cases caused by hæmorrhage in Henoch s purpura The hæmorrhage caused by trauma is, however, more likely to be under the peritoneal coat, where it would not easily lead to intussusception Secondly, intussusception may perhaps originate in a temporary local paralysis of gut caused by violence applied through the abdominal wall Walton[6] quotes the experiments of Nothnagel in which he induced intussusception by electrical stimulus, "invaginatio spasmodica," and by inducing local paralysis by crushing, "invaginatio paralytica" As clinical illustrations of "invaginatio paralytica," Walton quotes a case following a Richter s hernia and a case reported by Sherren,[11] in which a gangrenous portion of the transverse colon acted in the same way

It seems not unreasonable to suppose that violence applied through the abdominal wall may occasionally crush a small portion of gut so severely as to cause a temporary local paralysis and yet leave no obvious sign of injury Such is, I believe, the explanation of the case reported here and, perhaps, of other cases where a less convincing history of trauma is given

A CASE OF SYPHILITIC NEPHRITIS

BY H. B DAY, *M C*, M D LOND, F R C P LOND,
PROFESSOR OF CLINICAL MEDICINE EGYPTIAN GOVERNMENT SCHOOL OF MEDICINE *CAIRO* PHYSICIAN KASR EL-AINI HOSPITAL

THE following case of acute nephritis complicating secondary syphilis seems worthy of record, since the response to specific *treatment* was unusually rapid and complete

H M, an Egyptian tram conductor aged 20 was admitted to Kasr el Aini Hospital on Dec 6th 1919 for nephritis He stated that a fortnight previously he had begun to *suffer* from loss of appetite with occasional vomiting, and that a week later œdema had appeared, first in the scrotum and then in the face and whole body. *On* admission he *presented* the usual signs of nephritis. There was extensive œdema but no free fluid in the serous sacs, the urine averaged 1000 c cm per diem (vide chart) *had* a sp *gr 1015 and contained a* considerable amount of albumin (13 per 1000 Esbach) Microscopically, there were numerous casts granular and leucocytic, as well as bilharzia ova, *with attendant blood* and pus corpuscles Over the patient's body were scattered papules of a deep coppery hue There were snail track ulcers on the tonsils and a barely healed hard *chancre on* the penis Blood examination gave a positive Wassermann reaction The patient admitted noticing the chancre about two months before, but had taken no medical *treatment*, and was anxious to conceal his disease

Treatment consisted of intravenous injections of novarsenobillon, 0 45 g being given on the fifth *and* a similar dose on the twelfth *day after admission* The result was immediate and very striking Within a few hours of the first injection the urinary flow increased four fold and the diuresis with frequent micturition continued as shown on the chart

The œdema quickly subsided and inside a week the albumin had diminished to 1 part per 1000 Two days after the second dose of novarsenobillon, the patient had an attack of fever lasting three days which caused a temporary fall in the diuresis but did not increase the albuminuria which had so rapidly declined A fortnight after the treatment had begun the patient insisted on taking his discharge as he felt perfectly well and could not afford to lose his employment At this time the urine measured 2500 c cm per diem, had a sp gr 1013 *and contained* but a *trace of* albumin (under ¼ per 1000) with scanty granular casts The rash had largely faded, but no effect on the bilharziasis was apparent, ova were *plentiful* and hatched as freely as on admission

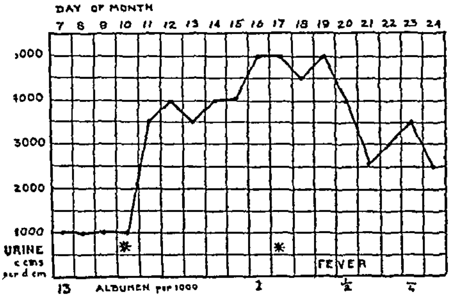

Chart showing quantity of urine passed per day in case of syphilitic nephritis ** Indicates intravenous injection* of 0 45 gm novarsenobillon

The diuresis appeared to be entirely derived from the retention of fluid in the body For within the space of 12 days the patient lost 20 kilos in *weight (over 3 stone)!* This amount—20 litres—closely corresponds to the excess of urine passed if we allow 2 litres a day of urine as the normal maximum output

The immediate effect of salvarsan therapy on this patient was so striking that there can be little doubt that the nephritis was entirely syphilitic in origin As in the majority of cases reported, nephritis appeared in the early secondary stage, about three months after infection I attribute the success of treatment (so far as it could be carried *out) to the* early use of adequate doses of the salvarsan compound instead of mercury It seems improbable that a nephritis appearing during specific treatment of syphilis would respond so favourably as this case where no previous treatment had been *received*

PERICARDIAL EFFUSION FOLLOWING THE INJECTION OF ANTIDIPHTHERITIC SERUM

BY C WILLETT CUNNINGTON, M B, B C CANTAB

THIS case is of sufficient interest to be worth recording

The patient, a boy, aged 10, presenting clinical and bacteriological evidence of diphtheria, was given on the fourth day of the disease an injection of 7000 units of serum His temperature was then 101° F The cardiac physical signs were normal Thirty six hours later the temperature rose to 103° The fauces had cleared, but there had developed well marked signs of a pericardial effusion, obvious *præcordial bulging*, dullness extending beyond the apex beat *to the line of the* anterior axillary fold Breath sounds absent over the front *of the upper lobe* of the left lung There was no pericardial friction audible at any time in the illness The pulse rate was 120, and its quality good and rhythm regular

Dr W W Jameson (medical officer of health for Finchley) to whom I showed the case as a curiosity, *agreed in the* interpretation of the signs, which suggested a passive effusion into the pericardial sac rather than an inflammatory pericarditis

The signs of fluid gradually diminished and disappeared after ten days The diphtheria itself proved a mild attack *and cleared up without any* further complications There was no serum rash

Dr Jameson *informs* me that he has been unable to trace in the *literature any record of a similar occurrence* following the injection of serum

ROYAL SOCIETY OF MEDICINE.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

A MEETING of this section of the Royal Society of Medicine was held on April 23rd, Mr. J. P. LOCKHART-MUMMERY, the President, being in the chair.

Renal Dwarfism with Bony Changes.

Mr. D. H. PATERSON read a paper on Chronic Intestinal Nephritis associated with Infantilism and Curious Bony Changes. After briefly reviewing the literature of the subject he described three cases:—

Case 1 was that of a boy, aged 11 years, who was admitted to hospital in January, 1917, for deformity of the bones of the legs and arms and inability to walk, because of knock-knee. The condition had been present for four years. He was healthy at birth and breast-fed for 9 months, but afterwards kept on fluid food longer than usual since he disliked solids. He had always been fond of fruit, and had been a great drinker of water. The father and mother and the four other children of the family were all healthy, and showed no bony deformities, nor was there any family history of kidney disease. Until the age of 6 he had been quite well, but then had an illness which started acutely, and was accompanied by feverishness and vomiting. After this he did not seem so well, and at the age of 7 it was noticed that his legs were bent, and he became progressively more knock-kneed. He was treated for rickets by splints, but at 7½ years old was admitted to the local hospital, where it was found that he had kidney disease. The bones of his legs were broken and re-set, and from that time he had not been able to walk. When admitted to the Hospital for Sick Children, Great Ormond-street he was found to be a very small, pale child, and very thin. The legs were markedly deformed, with bowing outward and forward of the femora and tibiæ; there was also marked muscular wasting. An operation of double osteotomy of the femora was done and was followed by uræmia, which proved fatal. The urine, examined after operation, contained albumin and casts. X ray examination showed bony deformities. Post mortem the kidneys were extremely small and showed some cystic and fibrotic changes. The only other organ which was found abnormal was the heart, which was dilated.

Case 2 was that of a boy, aged 1 year and 9 months, admitted to hospital in September, 1919, with deformity of the ankles and wrists, which had been present for 10 months. There was no other case of deformity in the family. The boy had been breast-fed until 11 months old, and had never been able to take any solid food. When a year old he was fat and could stand, but was small. He seemed to lose power in his legs, and later it was noticed that his arms gave way also, and he had no strength in them. They afterwards became permanently flexed. After an illness in March, 1919, associated with constipation and vomiting, he steadily lost weight. When admitted he was seen to be a very much underdeveloped and under-nourished child, and weighed 10 lb. 8 oz. He seemed to be bright and intelligent, but did not speak. The thorax was long and narrow in shape, and there were parietal and frontal bossing, an open anterior fontanelle, beaded ribs, and Harrison's sulcus. The liver and spleen were both enlarged. The back was straight, but the limbs were extremely deformed; the femora were bowed and the patellæ rotated outwards; the tibiæ were very bowed, and the radii and ulnæ showed a like deformity. The hands were held in accoucheur position, but there was no suspicion of tetany. Respiratory, circulatory, and nervous systems were normal. Ten days after admission the child's diet was increased to solid food, including minced meat and potato. He then developed uræmic convulsions and died. Post mortem the left kidney was found to be extremely small, and appeared to be cirrhotic. The right was slightly larger, but was also abnormal, its condition suggesting old inflammation, and its capsule stripping with difficulty. Both suprarenals were enlarged. The bones showed changes typical of rickets at the epiphyses. Microscopically the sections of the kidney showed a condition of fibrosis to a marked degree, the kidney substance being replaced entirely in some areas by fibrous tissue. The arteries were greatly thickened and many of the glomeruli were obliterated. In some places the tubules showed enlargement as though in an early stage of cyst formation. The kidneys weighed about a drachm each.

Case 3 was that of a girl, aged 7½, admitted for the contracted legs and bent wrists which had been present since birth. There was no family history of a similar condition. She was a premature child, born at the seventh month of intrauterine life and had been breast-fed for six weeks, after which time she was given cow's milk and seemed to thrive quite well. She had never walked. At 3 years a tenotomy had been done as her feet were being drawn up. On admission she was found to be 34 in. in length. Her head was square and bossed. The shoulders were sloping and rounded, and the clavicles curved antero-posteriorly. There was possibly an old fracture of the right clavicle. Flexion, extension, and abduction of the shoulder-joint were all limited. The humeri were very thin. The radius and ulna on each side showed great enlargement and deformity at the lower ends, giving the impression of old fractures which had united in bad positions. The thorax was long and narrow and pigeon-chested, and the ribs were beaded. The liver reached to two fingers'-breadth below the costal margin; the spleen was just palpable. The legs would not fully extend at the hips, and there was considerable genu valgum with rotation of the patellæ outward, the knees not being able to be fully extended. The tibiæ were small and sabre-shaped, and the lower ends of the tibiæ and fibulæ were much enlarged. Dorsi-flexion of the feet beyond a right angle was impossible. The back was straight. The urine contained a trace of albumin, but no casts. Mentally the child was very backward and seldom spoke. The phenol-sulphophthalein test indicated a great retardation in the secretion of the kidney. The Wassermann reaction was negative. An attempt was made to correct her bony deformities, but the left leg was refractured while being manipulated. Two days before her death she developed fine tremors of her hands, and a large amount of albumin was present in the urine. The urea was 0·3 per cent., and the nitrogen excreted as ammonia was to that excreted as urea as 1 to 10. Creatinin equalled 8 mg. in 10 c.cm. of urine. The child became comatose and died, passing no urine during the last 12 hours of her life. The cerebro-spinal fluid was normal but for a greatly increased amount of urea. The kidneys, post mortem, weighed 12 drachms each, and the suprarenals 2 drachms each. The kidneys were cirrhotic, their capsules stripping with great difficulty, and on section several small cystic spaces could be seen. Microscopically there was marked increase of fibrous tissue throughout the kidneys and a tendency to cyst formation, the tubules being greatly enlarged and filled with colloidal material. The glomeruli were fibrosed in places.

Attention was particularly drawn to the bony deformities. These, he considered, were quite unlike those of rickets; the epiphyseal lines were straight, and the radiographs distinct from those of rickets. Below the epiphyseal lines there was a stippled appearance, which the microscope showed to be due to cartilaginous callus with partly formed bone present in the islets. The same appearance might be seen in rabbits at the site of a fracture. One explanation of the picture might be that it indicated the repair of multiple fractures by the bone throwing out cartilaginous callus at their sites. Certainly the radiograms seemed to show that there had been multiple fractures on the diaphyseal side of the epiphyseal line.

Dr. MORLEY FLETCHER said that he had not seen the type of deformity of the bones just described. He showed a girl, aged 14, who had been backward in physical development since infancy, and had suffered from polyuria. She was small, weighing only 35½ lb., with a pallid face and poor nutrition. Her intelligence was good. There were no signs of puberty, and her appearance was that of a girl aged 5 or 6. The systolic blood pressure equalled 240 mm. Hg. The left ventricle was hypertrophied, and the aortic second sound accentuated. The radial pulse was thin and wiry. The only bony deformity was a slight genu valgum. The urine was acid, its specific gravity 1010, and it contained 0·3 per cent. of albumin and a few granular casts. The *Streptococcus fæcalis* had been grown from it. Albuminuric changes were present in the optic disc, and were of some standing. Speaking of these cases generally, he said that the degree of infantilism was perhaps more marked than in any other form of that condition, but the order of intelligence was rather high. A question of interest was the significance of globulin in the urine. It had been noted in two cases. The relationship between the renal infantilism and the bony deformity was obscure. It was clear that the renal changes began either in intra-uterine life or in early infancy. Syphilis could be excluded as the cause. A possible explanation might be infection of the urinary tract.

Dr. H. C. CAMERON referred to a very early case described by Davies Colley in about 1880 under the title "Dwarfism and Extreme Deformity." He had himself shown a case where the fibrosis was combined with a horseshoe kidney, and suggested that the two might be ætiologically associated. He had under his care at present a case which was very characteristic in appearance and with similar bony changes, but without albuminuria. A practical point had been emphasised by Barber—namely, the danger of operative interference, for uræmia was likely to follow.

Dr. F. PARKES WEBER drew attention to a group of cases included under the term diabetes insipidus in which some infantilism is present. The differences were that in this group the degree of infantilism was not very great, there was an absence of organic disease of the kidneys, the faulty organ was probably the posterior lobe of the pituitary gland, and the Wassermann reaction was often positive, congenital syphilis probably playing a part.

Suprarenal Sarcoma.

Dr. WEBER read notes of a case of Suprarenal Sarcoma of the Robert Hutchison Type.

The patient, who had been ailing since November, 1919, was a cachectic and emaciated girl, aged 5 years, with enormous enlargement of the liver and with a remarkable dark-bluish ecchymotic bilateral swelling of the eyelids. She was nearly blind from post-neuritic optic-nerve atrophy on both sides. Death occurred in March, 1920. The necropsy showed a curiously lobulated, very sanguineous, and partly necrotic tumour of the medullary portion of the right suprarenal gland, some of the cortical portion of which still persisted as an outer covering. The tumour, which microscopically appeared to be a round-celled sarcoma, was as large as a big orange, and during life was completely hidden by an enormously enlarged liver, diffusely infiltrated with the tumour-cells. Both the ovaries and many of the abdominal lymph-glands were likewise infiltrated, but the cranium was especially involved, the metastatic growth being situated chiefly between the dura mater and the inner table of the skull. The condition of the optic foramina and the orbits, affected in the same way, doubtless accounted for the ecchymotic œdema of the eyelids and the post-neuritic optic-nerve atrophy.

In regard to differential diagnosis during life, chloroma and all forms of leukæmia were excluded by the blood examination. Scurvy was out of the question. But the fact that for a month the child had been given a teaspoonful of brandy, four times daily, suggested at first the possibility that the enlargement of the liver might be due to hypertrophic cirrhosis, and that the blindness might be accounted for on the supposition that the brandy had been adulterated with methyl-alcohol.

SECTION OF ANÆSTHETICS.

Anæsthesia for Thyroid Gland Operations.

A MEETING of this section of the Royal Society of Medicine was held on April 9th, Dr. HAROLD LOW, Vice-President, being in the chair.

Mrs. DICKINSON BERRY read a paper on anæsthesia for operations on the thyroid gland. Her remarks were based upon an experience of 700 cases of operations for removal of goitre. In the past chloroform and its mixtures had been used either throughout or for induction, but since 1912 Mrs. Berry had relied entirely upon open ether and had met with no fatality and little anxiety since confining herself to that anæsthetic. She advocated an anæsthesia as light as is compatible with the requirements of the operator. Atropine is used beforehand, but morphia is disapproved of by Mrs. Berry and a slow induction is practised. The operation begins when regular breathing is established, even if the conjunctival reflex still persists. When the gland is reached ether is withheld if the patient is absolutely quiet. The eyes may open spontaneously or talking occur, the patient remaining quite motionless. Dislocation of the tumour is a dangerous process in cases of severe dyspnœa; the anæsthesia is kept specially light at this stage. Straining should occur when the last ligatures have been tied, in order to show any points which might lead to post-operative hæmorrhage. Notes of cases illustrating the above and other points were read. Two groups of cases were described as offering special danger, those with much tracheal obstruction and those with cardiac trouble. For the former it was often necessary to use oxygen with the ether. The cardiac cases included those in which the heart was affected by long-standing dyspnœa, true exophthalmic cases and cases of goitre not typically exophthalmic but associated with cardiac symptoms.

Dr. J. F. W. SILK said that "team-work" was most important in these cases, and so was a light form of anæsthesia. He had found rectal oil-ether of great value, particularly in exophthalmic cases.

Mr. JAMES BERRY said that the anæsthetist should never begin the administration for a goitre operation until the surgeon had on gloves, gown, &c., and was absolutely ready to begin. It was occasionally necessary to perform the earlier stages of the operation very suddenly and rapidly on account of dyspnœa. In cases of dyspnœa it is well to ascertain to what extent the head can be extended without serious interference with breathing, and during the operation never to let it be extended beyond this amount. It is Mr. Berry's custom to have the head held firmly throughout and only turned under special directions. In cases of dyspnœa the anæsthetist should acquaint himself before operation with the exact position and shape of the trachea. A unilateral goitre displaces the trachea to the opposite side, curves it, and flattens it on the side of the tumour. The point of maximum compression is nearly always 1½ inches below the cricoid. The dyspnœa is always due to direct pressure on the trachea, and has nothing to do with irritation of recurrent laryngeal nerves. In cases where the heart is seriously affected its condition should be ascertained by X ray and electrocardiograph examination. Mr. Berry said that he was using local anæsthetics less and less for goitre operations, and relying more and more upon light ether anæsthesia.

Dr. J. S. GOODALL thought the performance of any thyroid operation, except simple ligation, under local anæsthesia undesirable on psychic grounds. Any local anæsthetic containing adrenalin might induce auricular and even ventricular fibrillation. He had examined the hearts of many patients before, during, and after thyroid operations, paying particular attention to: (1) Degree of myocardial exhaustion; (2) amount of dilatation; (3) presence of definite myocardial degeneration; (4) height of systolic blood pressure. Electrocardiographic and X ray examination, together with mapping out of the field of cardiac response, are essential in estimating the condition of the myocardium.

Dr. J. BLOMFIELD said that he used open ether for these cases, but relied more than the reader of the paper upon preliminary injection of omnopon, scopolamine, and atropine. Many surgeons were uncomfortable if as light a degree of narcosis as that described by Mrs. Berry were employed. He related a case showing the necessity for the surgeon being ready to operate from the moment induction of anæsthesia was begun.

Dr. F. E. SHIPWAY preferred intra-tracheal ether in all goitre operations except the exophthalmic cases. All difficulties were removed by this method, particularly those due to pressure of the tumours upon the trachea, and a very light narcosis could be accurately maintained, permitting straining or coughing at the surgeon's desire. For exopthalmic cases he favoured oil-ether *per rectum*, preceded by large doses of morphia and scopolamine; the direct laryngoscope and catheter should be at hand.

Dr. HAROLD LOW said that the cases requiring special treatment were those in which the trachea was pressed upon and those with constitutional symptoms. He considered the ideal anæsthetic to be either intra-tracheal or rectal ether; next to these he placed open ether used to maintain a light degree of narcosis. Only skilled anæsthetists should undertake goitre cases.

Dr. F. S. ROOD divided goitre cases into three groups: (1) simple tumours or cysts with no respiratory obstruction and no toxæmia; (2) patients with stridor and possibly definite respiratory obstruction and heart failure; (3) cases of exophthalmic goitre. In the first group there is nothing special about the anæsthetic. In the second group he preferred chloroform to ether; in the exophthalmic cases he though it most important to guard against the element of fear; a preliminary injection of morphia and scopolamine was most useful.

TUBERCULOSIS SOCIETY.

AT a general meeting of this society held on April 26th, with Dr. H. DE CARLE WOODCOCK in the chair, Dr. CLIVE RIVIERE read a paper on

Some Thoughts on the Treatment of Pulmonary Tuberculosis.

He begged to be forgiven if, in attempting to provoke thought, he appeared to wander superficially over a very wide subject. The world in general had recently been talking of the failure of sanatorium treatment. The sanatorium had not been a failure, but was a definite and successful method of obtaining a cure. The rest and exercise practised in these institutions caused auto-inoculation. This, under medical control, raised tolerance, and was nature's own method of obtaining a cure. The downward progress of uncontrolled cases was due to excessive auto-inoculation which did not stimulate a beneficial immunising response. Sanatorium treatment as practised was too short, but in spite of this many cases returned arrested. If given the opportunity the cases would be legion which would respond to this treatment. It is after the patient's return home that the sins are committed, when, owing to the lack of any after-care system, he returns too soon to unsuitable over-strenuous work and passes out of control. The gains made in sanatorium in this way fail to be consolidated and the institution receives the blame. Cases must be obtained early and Dr. Riviere was of opinion that many patients with hilus disease had been treated in the early stages as neurasthenics. After-care was one of the most difficult problems, because the patient resents any further control after his return home. The system, however, is essential because the ultimate permanent cure is a matter of years, not months.

Graduated exercise was first started in Germany at the sanatorium of Brehmer. This was followed by Dettweiler, who preferred to call his method graduated rest. Much controversy and two distinct schools of thought had resulted; the one in favour of exercise in preponderance, the other in favour of an excess of rest. In this country, probably as a result of following Otto Walther, of Nordrach, the exercise treatment had predominated and it had been further developed by Paterson at Frimley. Graduated exercise should in any case only be commenced when cases become afebrile; fever must be controlled by rest. Both are essential, but where the two meet is still a matter for investigation. The vigorous exercise régime is more suited to the English temperament, but each case must be considered on its merits.

Recently the treatment by reactions from exercise and tuberculin had extended to the use of chemical agents. Gold, copper, arsenic, nickel, and cobalt had been tried with no very definite results. Specific action upon tuberculous tissue had not yet been proved. The cacodylates caused marked primary and secondary reactions with apparent improvement. It was questionable whether copper exercised any selective action upon tuberculous tissue and gold certainly did not, but it appeared probable that improvement occurred as a result of the class of case treated and did not depend upon the drug used. It has been claimed that antipyretics in small doses raise tolerance, but this is probably due to reduction of fever causing improvement in general condition and better appetite. These results would be quite well obtained by exercise, but here difficulty arose in control.

Discussion.

Dr. H. A. ELLIS said that in Coolgardie Sanatorium, Australia, exercise had proved almost universally bad, because of the high atmospheric temperature. In Middlesbrough the opposite had been his experience. He had found the condition of the skin an excellent guide to the amount of exercise to be allowed. In the early-age cases of Brownlee exercise was universally bad. Tuberculous cases could be divided into three classes: hypersensitive, sensitive, and subsensitive. Copper when injected intravenously combined with hæmoglobin and became inactive. He considered that it exerted a definite specific action upon tuberculous tissue.

Dr. HALLIDAY SUTHERLAND thought that rest treatment was run to death in Switzerland. There was an excellent increase in flesh, but no solid improvement in the disease. Sanatorium treatment was sufficient without adjuncts. He had tried copper without benefit. If a cure was to be a proved success it must be effective in all cases, including the advanced; no selection must be made. The fall in temperature in using colloidal copper was due to the peptone contained in it; it was doubtful what the active principle was.

Dr. L. J. SHORT said that as patients were unwilling to carry out treatment for a sufficiently long period in a sanatorium, an after-care labour colony became an indispensable part of the scheme.

The CHAIRMAN said that he had recently tried the effect of producing an extra-costal pneumothorax effect, by applying sandbags to the affected apices; but it was too soon yet to determine the results. He considered in X ray photographs that striæ, extending to the base of the lung, might be disregarded, but those extending to the apex were usually significant of a bad case.

Dr. RIVIERE briefly replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

Senile Urticaria Pigmentosa.

A MEETING of this section was held, with Dr. G. PEACOCKE, the President, in the chair, when Dr. M. DRUMMOND showed a case of Senile Urticaria Pigmentosa of 15 years' duration in a man aged 68. The condition, well seen on the arms and trunk, consisted of closely-set macules and plaques, the latter up to two shillings in size, pink, red to deep violet, disappearing on deep pressure. The duration of the individual lesions varied from half an hour up to several months. Factitious urticaria was marked, itching very slight. As the disease is usually limited to very early life, this case was not at first thought to be urticaria; the diagnosis lay between that and the erythemas. The patient was examined by Dr. Wallace Beatty, who had a similar case in an adult in 1919. Sections of skin were examined by Dr. W. D. O'Kelly, who reported the presence in large numbers of mast cells in the skin,—a condition regarded as pathognomonic by Brock, Unna of Hamburg, and Gilchrist of Johns Hopkins Hospital. The patient suffered also from auricular fibrillation and was treated by Dr. G. Nesbitt, who showed slides of tracings taken to demonstrate the condition.

Dr. BEATTY stated that he had seen a similar skin condition in 1919 in a healthy man of 32, the trunk and extremities being affected; duration ten years. Condition had been first noticed on the upper part of the chest, and spread gradually—the face, hands, and feet being spared. There was no irritation. The majority of spots were brownish in colour and not altered by pressure. At first sight the condition suggested a syphilide, negatived by history and duration. According to Darier it usually occurs in infants, and tends to disappear in eight to ten years. In 1905, at the French Society of Dermatology, the speaker had stated that the affection might begin in adult life, and was often a family condition. He had then showed slides of microscopic sections of skin showing numerous mast cells, also photographs of the condition in adults and in an infant.

Dr. WALTER SMITH objected to the name senile urticaria pigmentosa.

Dr. O'KELLY stated that he had never seen such large numbers of mast cells packed with basophile granules. There was no special distribution of the cells.

Dr. W. M. CROFTON suggested that cultures should be made from fluid obtained by blistering affected areas.

Dr. E. M. MAXWELL then showed a patient with Pituitary Tumour and Dr. H. F. MOORE read a paper on Diabetes Mellitus with Acidosis.

SECTION OF OBSTETRICS

A MEETING of this section of the Royal Academy of Medicine in Ireland was held recently, when Dr. E. H. TWEEDY, the President, read a paper on

Tubal Sterility.

The PRESIDENT showed his instruments for passing catgut through the tube. He said that a fine stiff needle with a blunt point should be used. It should pass first through the ovary, where the catgut should be knotted, then through the tube, and then through the mucous membrane. Mucous membrane should be sewn to mucous membrane. In every case of sterility the tubes, even though apparently normal, should be tested for permeability by the air test. The impervious part should be cut away. It had been suggested that the short tube would prevent pregnancy, but he had seen pregnancies in women whose tubes were certainly not more than 1½ inches long.

Dr. B. SOLOMONS said that Dr. Tweedy had dealt not so much with tubal sterility as with sterility in women with long tubes. He would feel very diffident about resecting tubes just because they were long. He blew them up with air when there was a kink and resected them not on account of length but because of disease. In excision for length did Dr. Tweedy get the excised part examined microscopically? The removal of the uterine ends of both tubes in these cases was a big undertaking in view of the difference in bore of the parts to be brought into apposition, that of the smaller end being only 1/25th of an inch. The instruments, he thought, would prove very useful. When resecting a tube he did not use forceps, but had special needles, the ends of the tubes being held one by him and one by an assistant, in an end to end anastomosis. But Dr. Tweedy was dealing with resection of the uterine ends of the tubes. This question of sterility embraced all the pathological conditions in the tube. Since October, 1919, he had seen many cases to prove that the tubes were usually at fault—many without gross lesions. It was difficult to know what to do in these cases. If the abdominal end was diseased, a new osteum should be made and the fimbriated ends removed, if the middle part, an end to end anastomosis, for which he used a long straight needle, resecting the tube when catgut had been passed through the lumen. In cases of disease of the uterine end the prognosis was very bad, especially if the condition was bilateral. He wanted to know what part of the ovary the catgut passed through before going through the tube, and if this step were necessary. He thought any ova in the neighbourhood should find their way into the tube without help.

Dr. S. SHEILL said that the first thing to prove was that a woman was really sterile, or successes might be claimed which were not earned. He was not sure that dilatation of the tubes with air was a sufficient test of the condition of the tubes. The only proof of sterility was a microscopic examination of the parts removed. With regard to the passage of the needle, if a false passage were made at the uterine end, it was possible that the epithelium would follow this false passage, especially if chromicised gut were used instead of ordinary six-day catgut.

Dr. H. JELLETT, the Master of the Rotunda, said that the apposition of the wide and narrow parts of the tube was the great difficulty.

The PRESIDENT, replying, said he hoped that by next year the technique of the operation would be greatly improved. Dr. Solomons dealt with the long tube. What he said was not that a long tube should be resected, but that a long tube which was obstructed, as most long ones were, should be resected. He had observed the greatest difference in the calibre of tubes in different individuals. As regarded the microscope test, serial sections would have to be taken of the 1¼ inches of tube removed, and the obstruction might only be $\frac{1}{100}$ of a millimetre. He thought the method employed by Dr. Solomons would lead to tubal pregnancy, as it had done in one case already, and also in one of the speaker's own cases where this method was employed. He described this case, in which he resected one tube for concretions, the other being fairly normal. The patient had a fixed retroversion. An end to end anastomosis had been done, and the patient returned to Steevens' Hospital still sterile. The abdomen was opened, and the anastomosis was found to have given way and the lumen to be closed. The tube was again resected and the woman appeared at the Rotunda Hospital with a tubal pregnancy on the side of the resected tube. It was possible to pass a big sound through the fimbriated extremity to the uterus, and the probe could pass over the ovum into the uterus. The other tube would not let anything through, therefore the technique was at fault. A continuity of epithelium was absolutely necessary.—Dr. SHEILL asked, if that were so, why did not ligating the tubes for the purpose of making the woman sterile prove successful?—The PRESIDENT: No such case had been reported in Dublin. Dr. M. J. Gibson and Dr. Solomons both got cases of tubal pregnancy. He used to agree with Dr. Solomons that this was due to inflammation, but now believed that the lack of epithelial continuity was at fault. Blair Bell had had a case of pregnancy after stitching the fimbriated extremity to the cornu of the uterus.

ROYAL MEDICO CHIRURGICAL SOCIETY OF GLASGOW.

Exhibition of Cases and Specimens.

A MEETING of this society was held on April 16th, Mr. A. ERNEST MAYLARD, the President, being in the chair.

Dr. G. HERBERT CLARK showed the two patients referred to in his communication to the society[1] of March 19th.

Dr. J. SCOULER BUCHANAN and Dr. WALTER W. GALBRAITH showed two cases of Articular Effusion into Both Knee-joints due to Congenital Syphilis. In the first case, that of a previously healthy boy aged 11, the only symptom had been a feeling of tiredness in the legs with little or no pain and swelling of the knees without tenderness or restriction of movement. However, he showed keratitis fissures about the mouth and pegged teeth. Both he and his father gave a positive Wassermann. In the second case, a boy aged 13 years, stiffness and swelling of the knee-joints were first complained of after a fall from a height on to his knees. Beyond a slight degree of "sabre blade" tibiæ the boy showed no evidence of congenital syphilis but both he and his father gave positive Wassermanns, and his mother gave a suspicious reaction.

Mr. ARCHIBALD YOUNG showed a case of Volkmann's Ischæmic Contracture of the Forearm, treated by manipulation and splinting. The patient, a boy, aged 11 years, was admitted to hospital in March, 1918, for a simple fracture of both bones of the forearm slightly above the middle. The arm and forearm were put up on an anterior (flexor) splint of moulded metal bent at right angles at the elbow (the forearm being fully supinated), supplemented by a corresponding moulded poroplastic splint applied to the extensor aspect of the forearm only. Six days later, on account of pain at the elbow and disability in finger movements, the splints were removed and put up less firmly. By March 22nd there was well-marked tendency to contracture of the fingers, and in spite of massage and passive movement, by Oct. 26th the patient had well-marked ischæmic contracture (Volkmann) and atrophy of all the muscles of forearm and hand, and was readmitted to hospital. Under an anæsthetic the four fingers were separately stretched and fixed fully, or almost fully extended, in individual moulded splints made of sheet tin, covered with lint. Maintenance of the palmar flexion of the wrist was obtained by a long metal splint and fixed on the extensor aspect of forearm and hand. A fortnight later the splints were readjusted, flexion at the wrist reduced, and extension at the metacarpo-phalangeal joints increased. After another fortnight a similar process was carried out. Twenty days later the fingers and wrist were freely manipulated and splints reapplied with the contracture almost fully corrected, and 16 days later the special finger splints were discontinued, a splint dorsiflexed at the wrist being applied on the palmar aspect of forearm and hand. Each readjustment of splints was carried out under general anæsthesia. Less than a week later this long splint was also removed and massage and electrical treatment were instituted. More than a year later the function of the limb was very good, but there was still disparity in muscular development of the two forearms, particularly as in the flexor pronator groups. There had been slight recurrence of the contracture, mainly of the flexor profundus. The speaker said that it might yet be desirable to renew the splinting for a time, but the final result would be most satisfactory.

---

[1] THE LANCET, April 10th, p. 817.

The PRESIDENT showed a specimen of Maier's Funnel-shaped (Trichterförmig) Hypertrophic Stenosis of the Pyloric Orifice removed by operation from an adult. The patient, a woman aged 36, was very thin, with abdomen somewhat distended, and a firm, movable mass, rather tender, palpable in the right iliac region. She gave a history of rapidly increasing emaciation, constipation, and latterly of pain in the right hypochondrium, followed by vomit shortly after taking food. On operation a freely movable pyloric tumour was found, associated with a greatly dilated stomach. In the belief that this was a growth, the pylorus with half the stomach was excised, and a posterior gastro-jejunostomy performed. The patient did well for four days, but later died of double pneumonia. The pathological report on the specimen stated that there was stenosis of the pylorus with marked hypertrophy of the muscular ring; no evidence of new growth or of recent or healed ulcers. Microscopical examination showed regular tubular glands and hypertrophy and a diffuse interstitial fibrosis of the muscular tissue.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

Expectant Treatment in Eclampsia.

A MEETING of this society was held at Leeds on April 16th, Mr. MILES H. PHILLIPS, the President, in the chair, when Mr. W. GOUGH (Leeds) gave an analysis of 61 cases of eclampsia at the Leeds Maternity Hospital during the last ten years. The average age of the patients, of whom 47 were primiparæ and 14 multiparæ, was about 26 years. Multiple pregnancies occurred three times and hydatid mole once; in one case only was there a history of previous eclampsia. Mr. Gough brought this subject before the society with a view to advocating the expectant method of treatment. In 5 cases the pregnancy was artificially terminated, and of these 2 died. In the remaining 56 cases the only treatment adopted was expectant, on the lines advocated by the Dublin and Glasgow schools. In a few cases delivery was hastened by forceps late in the second stage, but this was the only operative treatment. In 9 cases the fits commenced post partum, and of these 1 died. Of the remaining 47 cases 5 died, excluding 1 case where death was caused by a perforated gastric ulcer. As regards the children, in the cases where labour was induced, one child was born alive and four stillborn. Where no operative interference was carried out 24 were born alive and 21 were stillborn; in one the pregnancy was a hydatid mole, and the remaining case recovered from her eclampsia and went home undelivered. Mr. Gough was therefore convinced that much better results were obtained for both mother and child if labour was allowed to come on spontaneously.

The PRESIDENT congratulated the Leeds Maternity Hospital on their excellent results. The maternal mortality was much lower than any figure he had seen published hitherto. At the Jessop Hospital, Sheffield, Dr. J. Chisholm had looked up the cases and found that the mortality over a similar period was nearly 25 per cent., the total number of cases treated being 177. However, it varied very much from year to year. He thought Cæsarean section good treatment in carefully selected cases, and had obtained several very satisfactory results therefrom.

Dr. J. W. BRIDE (Manchester) had analysed the cases treated at the St. Mary's Hospitals, Manchester. During the last ten years 220 cases were admitted, and the mortality was nearly 33 per cent. The figure varied much from year to year, in one year being as low as 12 per cent., and it was of interest that in that particular year the pregnancy was generally terminated by rapid dilatation of the cervix and immediate extraction.

Dr. J. B. HELLIER thought that Cæsarean section was sound treatment if carried out by competent operators and in suitable surroundings. Where this was not possible the expectant method was much safer.

Dr. DANIEL DOUGAL (Manchester) was of the opinion that cases varied so much in type that one method of treatment was not always the best. He had tried Cæsarean section with disappointing results in cases chosen because of their severity. He thought it possible that Cæsarean section might give the best results if carried out in every case at an early stage of the disease.

Dr. GOUGH briefly replied.

AN ordinary meeting of the West London Medico-Chirurgical Society will be held to-day (Friday) in the society's rooms, West London Hospital, at 8.30 P.M., the President, Dr. Herbert Chambers, in the chair, when a paper will be read by Mr. Sydney G. MacDonald on Tuberculous Affections of the Urinary Tract.

Reviews and Notices of Books.

GYNÆCOLOGY FOR STUDENTS AND PRACTITIONERS.

Second edition. By T. W. EDEN, M.D., F.R.C.S. Edin., F.R.C.P., Obstetric Physician, Charing Cross Hospital; and CUTHBERT LOCKYER, M.D., B.S., F.R.C.P., F.R.C.S., Obstetric Physician to Outpatients, Charing Cross Hospital. London: J. and A. Churchill. 1920. With 513 illustrations and 24 coloured plates. Pp. 928. 38*s*. net.

IN the revision of the second edition of their book the authors have added to the section on ovarian gestation. Stress is laid on the distinctive naked-eye appearances of an ovarian molar pregnancy, especially on the sharp line of demarcation between the cap of ovarian tissue overlying the mole, a dark plum-coloured cyst with smooth walls. A description has been added of epispadias, hypospadias, and ectopia vesicæ in the female. A section is also devoted to a description of the operative procedure appropriate for a case of epispadias. There are some alterations in the section on ectopic gestation, including an account of the rare occurrence of a multiple pregnancy in an ectopic gestation.

In considering the after-results of the operation of extended abdominal hysterectomy for cancer of the cervix the authors call attention to Weibel's statistics showing that recurrences may take place in some 7·7 per cent. of such cases between the period five to seven years after the operation. They estimate the relative percentage operability of vaginal hysterectomy to that of the extended abdominal operation at about four to one. Some new matter has been added in the section dealing with the enucleation of broad ligament cysts. In our opinion, if it is necessary to drain through the posterior vaginal fornix because the bleeding cannot be completely controlled, it is better to use a gauze plug rather than the rubber tube recommended by the writers. The operative treatment for dealing with a rectocele has been inserted and a few minor alterations in response to some criticisms on the first edition have been incorporated. There are five new coloured plates illustrating unruptured tubal pregnancy and a retro-uterine hæmatocele, kraurosis vulvæ, erosion of the cervix (the legend spoilt by the needless addition of the misleading name pseudo-adenoma), endocervical and corporeal cancer, and a fine plate of a lipoma of the broad ligament.

A very good book, but—we must add—unfortunately growing too large for the student to read, even if not too large for the specialty with which it deals.

A TEXT-BOOK OF OPHTHALMIC OPERATIONS.

Second edition. By HAROLD GRIMSDALE, M.B., F.R.C.S., and ELMORE BREWERTON, F.R.C.S. London: Baillière, Tindall, and Cox. 1920. Pp. 438. 18*s*.

THERE are two objects which a book of this sort may be expected to fulfil: first, fully to describe those operative procedures which the author as the result of his experience believes best calculated to attain the desired ends; secondly, to give an intelligible though not detailed account of so many of the other operations which are practised or have been described as may conceivably be of use to the ophthalmic surgeon. A book such as Meller's, in which the former object is prominent, makes the more interesting reading, but the latter object has its importance also. The young ophthalmic surgeon, if he is wise, will never undertake an operation without taking trouble to understand the advantages and drawbacks of the various procedures and modifications adopted by different operators. In the second place, having decided on the particular method which he means to adopt, he will read up a full description of this method, not entirely trusting to any text-book but consulting original papers. The extent to which the text book of Grimsdale and Brewerton attains this double object is very considerable, and it is not the least of its merits that at the end of each chapter a list of references is given to the original descriptions of the operations summarised in the text. This feature cannot fail to be useful to every ophthalmic surgeon who has access to a library.

The first edition of this book appeared in 1907, and the advance in the technique of ophthalmic surgery amply justifies a new edition. There is not a chapter in which new matter of importance is absent. The great advances in the operative treatment of glaucoma in recent years have necessitated the entire rewriting of this chapter. The new methods for dealing with contracted sockets by means of "epithelial inlays" and for providing new eyelids by means of "epithelial outlays," which were evolved during the war, are also described. The removal of foreign bodies from the interior of the globe is another subject on which much experience has been gained during the war, and a new chapter describes the methods of using Haab's magnet, the ring magnet, and the small magnet

In all, some ninety pages of new matter have been added, but the book remains eminently practical, and scant space is devoted to operations, which, in the authors' opinion, are useless, such as many of those devised for the cure of detached retina The illustrations are diagrammatic but intelligible. We could wish for more pictorial help in the case of some of the more important operations, notably trephining for glaucoma The book is a good and practical guide to operative procedures on the eye

LA GÉNÉRATION HUMAINE.

Ninth edition. By Dr. G. J. WILKOWSKI. Paris A. Maloine and Son. 1920 With 3 coloured plates and 108 illustrations in the text Pp 224. Fr 22

THE ninth edition of this popular work has been brought up to date by the inclusion of recent advances in our knowledge of the anatomy and physiology of the urogenital system A postscript on organo therapy has also been added, and we gather from this that our French colleagues have utilised the various glandular extracts to a far greater extent than we have Unfortunately we cannot comment on the success which has attended their efforts, for the results are not recorded.

The author is careful to point out that the book is not intended to replace the usual text books on the subject, and as an adjunct to them we feel that this book is most useful. The fact that it has been translated into Spanish and Finnish shows that its popularity is not confined to France. Historical anecdotes abound in the work, and make it more attractive than the ordinary text books on the subject The illustrations are good and the coloured plates excellent

HANDBOOK OF ANÆSTHETICS.

By J. STUART ROSS Edinburgh E and S. Livingstone 1919. With illustrations Pp 214 7s 6d

ALTHOUGH there are many little books on anæsthetics this addition to their number is welcome, for it is eminently readable. It is less taken up with detailed description of apparatus and of procedure than are most similar works, and for this reason is more pleasant to peruse though, perhaps, it loses in the same degree in usefulness to the beginner. The general principles which should guide the anæsthetist are clearly laid down, and he is made to understand them by an excellent account of the physiological knowledge on which those principles are based. In this chapter the author draws attention to a fact that is often overlooked. In describing the fall of blood pressure that accompanies narcosis he shows how this is due to some extent to the anæsthesia, comparable with the fall in natural sleep, apart from the action of the anæsthetic drug *per se*. Profiting by recent experience Mr. Ross gives an account of the treatment of shock among the casualties of the war. Discussing the causation of stridor the author expresses his belief that it may be due to morphine given prior to anæsthesia. He gives a capital account of the causation and the prevention and treatment of asphyxia. Mr. Ross evidently values and uses frequently the mixture of chloroform and ether (C_2E_3), and gives detailed directions of the correct way to employ it in conjunction with and in aid of "open ether." He approves of routine administration of morphine and atropine before anæsthesia In the account of rectal administration of ether he does not, we think, lay stress enough on the slowness with which the injection should be given, and on the time that should be allowed to elapse if the best result is to be obtained The mixtures of nitrous oxide and ethyl chloride have a small chapter to themselves. They appear to be more in favour in Edinburgh than in most other places, yet they are of undoubted service in dental practice, and might be more frequently employed with advantage Brief chapters on local and spinal anæsthesia are contributed by Dr. Quarry Wood, one on intratracheal anæsthesia by Dr Torrance Thomson, and an introduction by Dr Alexis Thomson.

HANDBOOK OF PHYSIOLOGY.

Fifteenth edition By W D HALLIBURTON, M.D., LL D, F R C P, F R S, Professor of Physiology, King's College, London London John Murray. 1920. With nearly 600 illustrations in the text, many of which are coloured, and 3 coloured plates Pp 936. 18*s*.

THE last edition was issued in 1919, and about nine months thereafter the author received an urgent request to prepare another and this is the result The new anatomical nomenclature and the appendix on War Diet (the latter written in July, 1918) are still retained. The author states that the changes are of "a minor kind." This we substantiate after comparing generally the present edition with its immediate predecessor The number of pages, the pagination, and number of illustrations are unaltered. The only change in illustrations we noticed is on p 337, where a figure of the structure of the thyroid and parathyroid gland is substituted for one of the thyroid As to the text itself we have been able to discover only very minor changes, such as those on p 342, on the suprarenal gland, on p 464 a slight change in the description of hæmopyrrol, and a few lines added on p 504 about reflex secretion. The reference to vitamines on p 905 of both editions is not mentioned in either index Obviously this work retains its well deserved popularity, and it is well entitled to, even though we failed to find an exposition of the more recent discoveries about "shock," intravenous injection of gum arabic, or any references to the work of Cushny on renal secretion

LA PHYSIOLOGIE

Par MAURICE ARTHUS, Professeur de Physiologie, Lausanne. Paris. Masson et Cie 1920. Pp 430. 10 francs.

THIS is in no sense of the word a text book, nor does it pretend to replace or even complete such a work, rather is it written to expound the actual state of the science, to mark its successive stages of development, its methods, its results, and to indicate the lines along which progress in the future is to be anticipated The author found his inspiration one day long ago in the romantic region of Sainte Geneviève, in the Quartier Latin, on reading Claude Bernard's "Lectures on Physiology Applied to Medicine" First the bald anatomical facts and the obvious movements of the body as they can be observed and studied by the unaided eye are attractively and clearly described—the chiefly physical facts being first dealt with—movements of the pupil, respiratory, heart, intestinal movements, and so on. Then follows the application of the graphic and photographic methods to the study of mechanical facts. The experimental method and its results are described, the importance of the animal selected being emphasised. Much attention is given to the effects, immediate and remote, of removal of organs, the suppression and modification of the functions of organs by drugs, cutting off the circulation, and other means. Excitation and stimulation of various kinds and of different organs are described, and then various "experimental devices," such as fistulæ, grafting, and their results. In this chapter the author describes Beaumont's famous observations on Alexis St. Martin, as being made by "Elie de Beaumont," a strange mistake for plain William Beaumont. After experimentation come interpretation and explanation of the results, with numerous instances and astute discussion and examples of analysis of experiments. A short excursus is made into the realm of pathology, cell life, physico-chemical phenomena, nervous and humoral mechanisms, including the hormone doctrine, and so on to the study of intoxications, which chapter brings this charming exposition to a close. The work is written in such clear, idiomatic, easily understood language, that it might well be read by anyone wishing to improve his knowledge of French, apart altogether from the fascinating coup d'œil which it gives of "la Physiologie" as the basis of medicine and hygiene. French writers have a genius for lucidity, but M. Arthus possesses this admirable quality in quite an exceptional degree. We have enjoyed both its comprehensive and critical survey and its lucid exposition.

PHYSIOLOGIE NORMALE ET PATHOLOGIQUE DES REINS.

Second edition. Par L. AMBARD, Professeur à la Faculté de Strasbourg. Paris: Masson et Cie. 1920. Pp. 368. 18 francs.

THE general plan of this monograph remains the same as when it was reviewed in THE LANCET of July 11th, 1914. The title might lead one to suppose that Professor Ambard had written an ordinary text-book on renal function. Not so, for this is rather a personal contribution to certain aspects of the subject. There is an extensive array of observations made by the author himself and some of his colleagues, first on the physiological side as to elimination by the kidneys by a process of diffusion of various alcohols, acetone, and chloroform, and more especially of experiments to determine the maximum concentration of urea, and the limits and variations of elimination by secretion of ammonia, iodine, SO_4, methylene-blue, glycerine, glucose, chlorine, water, and other substances. The author attempts to find a mathematical expression for the limit regulating the extent of each of these excretions, and seeks to explain how excrementitious substances do not accumulate in the blood, and how the blood maintains nearly a uniform composition. To this end the kidney is an organ which acts for the most part autonomously; indeed, as if it were not in relation with the central nervous system. About one-half of the text is devoted to various forms of nephritis; the author abandons the old histological classification and adopts that of Widal, which is explained in the text. The phenomena attending nephritis with œdema, azotemic nephritis, and mixed forms of nephritis are described, together with data for their prognosis. A short but important chapter which should be studied by surgeons is that devoted to the exploration of the renal functions in urinary surgery. This monograph embodies a large amount of research along specific lines, and is intensive rather than extensive in its application to clinical medicine, and as such will be specially interesting to those whose work lies in the domain of diseases of the kidney.

ANNALS OF MEDICAL HISTORY.

Vol. II., No. 2. Summer Number, June, 1919. New York: Paul B. Hoeber. Pp. 93–212. $2.50.

A PUBLISHER'S note informs us that "the publication of this issue has been greatly delayed by the recent printers' strike in New York City," which accounts for a somewhat belated notice of the same. The greater part of the number is devoted to papers dealing with Sir William Osler, who attained his seventieth birthday in July, 1919. Three of the papers, written during Osler's life, are respectively by Dr. Howard Kelly, Dr. John Ruhrah, and Dr. Fielding H. Garrison, and set forth the reasons why there is such a widespread desire to commemorate Osler's seventieth birthday, his influence on medical libraries, and his contributions to medical literature. In the fourth Dr. Harvey Cushing is able, owing to the delay in publication of the journal, to set before its readers a "laudatio" of Osler which is an admirable picture of the man and one, moreover, which shows that the biographer has no small portion of his subject's spirit. All the other articles contributed to the number under review are good, more especially "A House Surgeon's Memories of Joseph Lister," by Sir StClair Thomson, Sir D'Arcy Power's "The Oxford Physic Garden," and Major Reginald Fitz's "Napoleon's Camp at Boulogne." The last paper, with its interesting account of the medical organisation of the camp, shows yet once more Napoleon's astonishing faculty for taking pains about details.

THE MISADVENTURES OF ATHELSTAN DIGBY.

By WILLIAM FRYER HARVEY. London: The Swarthmore Press, Ltd. 1920. Pp. 191. 6s.

Athelstan Digby is a prosperous Yorkshire manufacturer, a bachelor, and a good citizen, whose keen enjoyment of life and undiminished mental energy at 55 years of age lead him into all kinds of innocent and entertaining adventures. The interest of the book from the medical point of view is the internal evidence that the author is himself a medical man. The comparison between the dietetic habits of the squire who "drank port, and his headaches were in the morning," with Digby's brother who, "a teetotaller and a somewhat immoderate eater. usually had his headaches at night," betrays professional knowledge as well as the description of the circumstances which led up to Mr. Digby passing an hour or two on a stretcher in the hospital mortuary, where "Simeon" performed operations, "very neat; large, clean incisions, and no anæsthetics." The book will agreeably fill up a leisure hour.

THE LINK BETWEEN THE PRACTITIONER AND THE LABORATORY.

By CAVENDISH FLETCHER, M.B., B.S. Lond., and HUGH McLEAN, B.A., B.C., D.P.H. Cantab. London: H. K. Lewis and Co. 1920. Pp. 91. 4s. 6d.

THIS little book is intended to guide the practitioner in his relations with the pathological laboratory. The diseases whereto pathological examinations are applicable are arranged in alphabetical order, and the various tests are cited with directions as to collection of specimens, the minimum times which should be allowed to the laboratory in cases of urgency, directions as to postage and packing, and so on. On the whole, the advice given and choice of tests are sound, although a number are quoted which are by no means generally accepted by pathologists of standing, such as the Arneth count and the determination of the coagulation-time of the blood. The presence of the pathologist at the bedside is advised in certain cases, but the essential value of making cultures direct from the lesion is by no means always clearly emphasised, a most vital matter in cases of influenza for instance. The influenza bacillus only lives for about half an hour outside the body. Very false ideas of the relative proportions of germs in culture may be arrived at in posted specimens. Mackey[1] found that immediate plating of post-nasal secretion yielded pneumococci 1000 colonies and 8 colonies of staphylococci, whereas the same swab posted and plated next morning yielded almost exactly the reverse proportions. When the pathologist comes to prepare his vaccine the importance of early plating is at once apparent. The initial vaccine doses recommended at the end of the book are in some cases obsolete; 2½ millions of pneumococci is one of these. Staphylococcal and gonococcal sera are, we believe, also useless therapeutically.

However, a book of this kind is badly needed. The present volume is fairly up to date, especially on the chemical side, although it does reveal, in all its nakedness, the failings of any scheme where the pathologist and his laboratory are not in close proximity to the practitioner and his patient.

THE LANCET.

LONDON: SATURDAY, MAY 8, 1920.

The Human Side of Industrial Efficiency.

PROGRESS in human affairs, if it is to be sure, must be based upon knowledge, and three stages are required to ensure advancement. First, knowledge must be acquired by laborious and painstaking research and investigation; then the knowledge acquired must be made known to those who can use it; lastly, it must be given practical application. Each step is of equal value to progress, whether that progress be economic, political, industrial, or medical. Not infrequently the acquirement of knowledge through research proceeds without reaching the field of practical application and, lying hid, becomes barren of results until, maybe at some distant date, it is dragged into the light of day. For this reason the double step of making known to the research worker what problems require elucidation, and of making known to those who want the knowledge what the research worker has found out, is one of fundamental importance. Yet for the most part it is not taken in either direction. A feeling is abroad to-day that, quite apart from the inconsistencies in the body-politic which have sprung up in modern society as a result of the industrial revolution, much ill-being and discontent exist which are due to lack of scientific knowledge as to the working of the human machine. "The living human body is surely," said Sir JAMES PAGET, "the most complex mass of matter in the known world"; it reacts in unexpected ways to new conditions; and has a habit of protesting vigorously when these conditions disturb the rhythm of existence. It reacts not merely as a physiological unit, but as a psychological entity, and must be studied from both points of view. The field of national welfare most concerned is that of industrial employment; in the past the attention of those who control the practical side of industry has been concentrated upon the processes of production, the invention of machinery, the improvement of plant, to the almost entire disregard of any study devoted to the human agency required to animate the whole. Here is vast promise of additions to knowledge. Research is in the first place needed into the working capacity of man, his liability to fatigue and to consequent ill-health, his physiological and psychological reactions to environment as represented by fresh air, hours of work, personal hygiene, cleanliness, and temperature. Action in this direction is already assured in this country through the work of the Industrial Fatigue Research Board, which is now definitely established and attached to the Medical Research Council. Thus we are in a better position than other countries. France, it is true, has appointed the Institut d'Hygiène Sociale and the Direction des Recherches Scientifiques to carry on work, but the activities incline to be restricted to laboratory experiments. In America the early promise given by the appointment of a Committee on Industrial Fatigue is not bearing fruit; information, the result of inquiries conducted in various industries by the investigators of the Board, is being published from time to time; but the seed falling by the wayside will be wasted unless steps be taken to cultivate it by organised effort.

We therefore learn with pleasure that steps are to be taken to this end, and that a National Institute of Psychology and Physiology applied to commerce and industry is being established. The position proposed for the institute is somewhat similar to that held by the National Physical Laboratory in relation to physical science, and the Royal Society at a later date may be asked to assume ultimate control. Close coördination with the Fatigue Research Board is promised, and should be assured by the presence among the supporters of the Institute of several members of the Board. Indeed, it is no secret that the Institute owes its inception entirely to the activities of certain members of the Board, and particularly of Professor C. S. MYERS. The promoters of the Institute are now appealing to industry for financial support, and this ought to be readily forthcoming, for there exist here possibilities of incalculable value to employers and employed. The Institute, we learn, is not established for profit, but all funds are to be used to promote a more effective application of national energy, and a correspondingly higher standard of comfort and welfare for the worker. The medical profession, with vision for a healthy race, cannot fail to be keenly interested in this new venture. If successful in reducing only to some small extent the wear and tear of daily industrial toil, it will proportionately leave the resisting power against ill-health and disease stronger, lessen the proportion of deaths in the prime of life, and lighten the heavy burden of preventable invalidity. Although, and at first sight, the title, aims, and objects of the Institute seem to apply only to industrial affairs, properly conceived we have here a most practical venture in the realm of preventive medicine. To study the economics of the human machine; to fit individuals according to their capacity into occupations for which they are naturally adapted; and to recognise and deal with the first symptoms of disability before a diagnosable syndrome of disease appears—these things must be of incalculable value to industry and commerce, and, incidentally, they will lay down principles and establish standards applicable to every phase of life. Here we have preventive medicine as an economic asset in daily life brought boldly into the regions of industrial profit and loss.

The programme of the institute is so extensive as to make us wonder at the moderation of the promoters in only budgeting for an expenditure of £10,000 a year. The establishment of well-equipped laboratories is proposed to investigate motion study and rest pauses, mental and muscular fatigue, and selection of workers, and in them statistical research will be conducted. Training courses and lectures are to be provided; investigations undertaken in industrial establishments; the health, comfort, and welfare of workers are to be studied; propaganda work is to be set on foot. Clearly, all cannot be carried out at once. We note, therefore, with approbation, that at the outset special attention will be paid to devising tests of individual mental and physical ability, so that each person may be advised as to the occupation for which he is best fitted. Our present methods of choosing life's work are confessedly imperfect. A father compels a reluctant son to adopt the parental job; some passing boyish fancy or temporary friendship influences a lad to make a wrong start; local demands for labour decide the choice for many, and so the process of trial and error, of hit or miss, goes on. The result is seen in the migration of labour from factory to factory, from mine to mine, from ship to ship, a migration annually equal in numbers to the whole of the working population; a result in itself eloquent of discontent, and representing an appalling economic loss in efficiency and in happiness, that happiness which Comte stated consists in doing the work for which we are naturally fitted. If the Institute only succeeds in this one matter it will abundantly justify its existence, and will do more to banish discontent and assure health—that health upon which human power depends—than any other social or economic activity. Searching for knowledge of man with one hand, and giving knowledge practical application with the other, the Institute might well choose Bacon's words for its motto, "Human knowledge and human power meet in one."

The Anæsthetist's Guerdon.

It seems clear, from the correspondence recently published in our pages, that there is a good deal of dissatisfaction felt by anæsthetists at the present time, but the remedy is not equally obvious. It is natural, of course, that the anæsthetist should find it necessary to raise his fee in accordance with the raised cost of all the necessaries of life, and here his necessity is only the same as that of large numbers of practitioners who have in various quarters publicly announced a rise in their charges to meet the advanced cost of living. This does not, however, appear to be the whole or even the chief reason which has set anæsthetists considering the subject of their fees. They suffer under certain difficulties, which are peculiar to their branch of practice, and which tell financially against a form of practice which has never been highly lucrative. Never, indeed, nearly so lucrative as its peculiar risks and demands appear to us to justify it in being. Some of these obstacles are, as Dr. Llewelyn Powell pointed out, unavoidable, and the chief of these is the number of appointments which an anæsthetist is obliged to refuse owing to the choice of time for operation not resting with him. Consequently he is often already engaged for the hour at which his services are requested, and the case is lost to him. This is a contingency which affects no other kind of medical man to anything like the same extent. Even here, though, we would venture to point out that the remedy is partly in the anæsthetist's own hands. He may make himself so desirable that either the surgeon or the patient will change the time rather than lose the anæsthetist of his choice. And, in fact, this we know happens in a good number of instances.

There is another direction in which the anæsthetist is apt to suffer. This lies in the duplication, so to speak, of responsibility towards him. Sometimes the surgeon, sometimes the general practitioner, and sometimes the patient, is responsible for the anæsthetist's fee. Very often the anæsthetist does not know which of the three it is, and he may find himself equally neglected by all. Again, it often happens that he is not consulted about the subject of his fee, and he may be presented later with a sum that does not at all represent his own ideas in the matter. Obviously, the anæsthetist should have the opportunity of naming his own fee, unless he is working with men whom he knows to be fully acquainted with his usual practice. The practical difficulty here often is that the practitioner or the surgeon, arranging the matter with the patient beforehand, has to include the anæsthetist. If he does not know him, and has not, as may well be the case, the time to communicate with him, he may easily misrepresent to the patient the expectations of the anæsthetist. Yet even in this case error should not be very serious, for surgeons and practitioners are well aware of the general custom as regards anæsthetists' fees. That this custom has hitherto been too niggardly we are strongly of opinion. The day has gone by when the anæsthetist, if he be a man who has devoted himself specially to this work, should count merely as an assistant and be remunerated on some such scale. His duties and those of the assistant at the operation differ in essential particulars. The anæsthetist has much and the assistant little or no responsibility. He acts directly under the guidance of the surgeon, but the surgeon rightly expects the anæsthetist to conduct his part of the case on his own initiative and responsibility, and looks to him, as part of that responsibility, to preserve the patient's safety, and to warn the operator of any encroachment upon it. The anæsthetist is held wholly, or partly, responsible for "regrettable incidents" that may attend on or follow operations. His remuneration should, in justice, be commensurate with his anxious position.

In attempting to arrive at a general principle upon which to fix the anæsthetist's fees some correspondents suggest that these should bear definite proportion to the surgeon's fee. This would, no doubt, supply an easy guide, but there are many instances in which it would, we think, provide a false standard. An operation may be short and easy, yet the condition or the physique of the patient may render the administration of the anæsthetic as difficult as can be imagined. The surgeon might justly demand in such a case a small fee for a small operation. The anæsthetist would obviously be hardly treated if his fee fell in proportion. Only in one element—that of time—is it possible to assess the surgeon and the anæsthetist fairly together. Both are naturally to be paid more the longer their services are required. We have glanced at a few of the difficulties which will occur to anyone who has read our correspondents' letters. We do not attempt to offer a solution, for we are convinced that by conversations with one another and with surgeons, anæsthetists should themselves provide a remedy for defects in the arrangements under which they practise. A modern writer has observed that the calling of the anæsthetist is "an honourable but not a fertile one." We know that it will remain honourable, and we hope to see it become more fertile.

◆

Pellagra and Diet.

EVEN the devastation of war may bring benefits to the human race. Among the solid advantages can be reckoned improved understanding of the biological values of foodstuffs. The part played by the building-stones of food, in the shape of proteins, carbohydrates, and fats, and the causation and avoidance of food-deficiency diseases have been studied with close attention and valuable results during and because of the war. The existence and importance of vitamines had, it is true, been demonstrated some 10 years before the war, and 10 years earlier still work on the etiology of beri-beri had prompted physiologists to study deficiency diseases. But the war has quickened all these studies, and pellagra is now receiving further and intensive scrutiny. Pellagra is an old and widespread scourge, obscure in origin, and long suspected of some relationship to underfeeding. Our military operations in Syria have brought to our notice large numbers of pellagrins amongst the prisoners. Given the material for study the British army has furnished many willing students. Few more exhaustive scientific investigations have been accomplished than those made by the Committee of Inquiry regarding the prevalence of pellagra among Turkish prisoners of war. The report of that Committee, summarised on p. 1027, contains definite negative and positive conclusions as to the causes of pellagra. The absence of proof of case-to-case infection or of location or local infection is of great moment. So, too, are the negative findings as to bacterial or protozoal infection. We come next to the positive conclusions. They are interesting, even if they bring us only to the threshold of new ideas and notable discoveries. Here is a disease in which it is suggested upon reasonable evidence that a prime factor is defective protein-supply to the body, and further, that protein-starvation may conceivably occur, even though an adequate quantity of protein is ingested. Admitting this to be possible, does pellagra depend on the quality of the protein, upon what is known as its "biological value," or does it depend on an inability of the individual to assimilate and turn to useful account protein of good biological value? The proteins have now been differentiated in regard to nutritive influence according to the amount and kind of amino-acid yielded on hydrolysis.

The report of the Committee propounds these questions, and leaves them for others to answer. Dr. A. D. BIGLAND, in his paper appearing last week in our columns on the Pellagra Outbreak among Ottoman Prisoners of War in Egypt, brings forward much first-hand information that cannot fail to advance our knowledge. There is undoubted value in his experiments, which corroborate those of previous observers who have failed to find any evidence of bacterial or protozoal infection either by cultural methods or by complement-fixation. Unfortunately, he was unable to complete his inoculation experiments or his investigation into the effect of maize of various qualities. He suggests that food-deficiency may predispose to, and some unknown toxin determine the occurrence of, pellagra. He points to the obvious similarities between this and Addison's disease, conjecturing that if a toxin is in some measure responsible it may act by attacking the endocrine glands, possibly the suprarenals. VISIWALINGAM,[1] observing that on the Malay peninsula pellagra attacked the Chinese only, came to a similar opinion, that faulty diet in itself could not cause pellagra, and that some superadded factor, probably a toxin, was required. BIGLAND notices as an arresting fact that the German army, apparently well enough fed, suffered from pellagra, whilst our army, fighting in the same country and under similar conditions, escaped.

Dr. J. I. ENRIGHT, however, in our present issue, deals more particularly with the outbreak of pellagra amongst German prisoners in Egypt. This author considers that the dietetic conditions under which these German pellagrins developed the disease "are sufficient to explode the food-deficiency theory as a predisposing factor." He advances the hypothesis that the parotid gland has some influence upon the development of pellagra. This may, indeed, be a hazardous guess, but the value of publishing these extensive personal observations cannot be gainsaid. The report of the Committee of Inquiry is a definite landmark in the survey of pellagra. Careful records of personal experience will help to carry us to the next stage. For the present all investigators will make the report their jumping-off ground. The connexion between dietetic deficiency and endocrine activity, which pellagra, famine-dropsy, and other deficiency diseases suggest, seems on the verge of conclusive proof by MCCARRISON'S experiments.[2] ENRIGHT, although he rejects the theory of suprarenal inadequacy as an explanation of pellagra and regards the food-deficiency theory as exploded, none the less expects to find the cause of the disease in a disorder of internal secretion, which interferes with protein metabolism in some such way as pancreatic insufficiency disturbs carbohydrate metabolism. Perhaps the link which will unite these divergent views is to be forged out of the hypothesis which makes an adequate supply of tryptophane essential to the secretion of adrenalin.

Annotations.

"Ne quid nimis."

THE POPULARISATION OF HEALTH QUESTIONS.

DURING this week a widely organised campaign of enlightenment on all questions of health has been undertaken by the Royal Sanitary Institute. Unquestionably the public is far more widely interested in health questions than was the case even a decade ago, while at the close of the nineteenth century health questions meant to the majority of the public nothing more than calling for a doctor or going to a hospital. We are witnessing to-day a great change of spirit; and if ever a new Government Department had an opportunity of public appreciation for the services embarked upon, it is the Ministry of Health. The public now knows that in the improvement of health conditions lies the solution of some of our most anxious questions of statesmanship and legislation. The institution of "Health Week" should certainly increase the driving force of all whose business it is to conduct public health matters and supervise medical and nursing administration. The publication by the Ministry of Health of a pamphlet[1] directing public opinion to the salient points of preventive medicine is therefore particularly timely. In this pamphlet the Chief Medical Officer of the Ministry sets out with clearness the need of an educated community, if the great work now before the Ministry is to obtain intelligent attention; and he specifies the directions in which an enlightened public opinion can help the individual and the State. The simple principles by which disease, personal and epidemic, can be avoided are detailed, so that the community should be enabled to assent to sanitary reform and government with open eyes, not grudgingly nor of necessity, but in obedience to reason.

THE AMERICAN HOSPITAL IN LONDON.

PROGRESS has recently been made, both in England and the United States, with the organisation of the American Hospital for London. Ex-President Taft has accepted the presidency in the United States, while Lord Reading, who from the first has taken an interest in the success of the hospital, has accepted a similar position in this country, with Lord Bryce as vice-president. The plans have been considered by an influential committee of American citizens resident in London, and steps are being taken to incorporate the institution according to the laws of the State of New York, when a campaign will be opened to raise a large endowment fund. At present a big building scheme is not feasible, but it is hoped to open a temporary building for the accommodation of patients early in the coming autumn. The scheme for the American Hospital, following on that conceived by Mr. Philip Franklin less than a year ago, is broad in scope. The resolution founding the hospital laid down that one of its most important aims was "to act as a link in binding together the two nations for the advancement of medical science as affecting the welfare of humanity." Actually, and in practice, the hospital is intended to become the principal research centre in Europe for American medical graduates who wish to proceed with their studies. For many years past American graduates who desired to continue their medical education in Europe settled almost as a matter of course in Berlin or Vienna, where special opportunities were freely placed at their command by the German and Austrian authorities. Since 1914 conditions have changed, and the leading members of the American colony in London have determined that American graduates who come to Europe shall find in London the facilities they were formerly offered on the continent. This decision has received the unqualified support of many leaders of the British medical profession, and the medical committee in Great Britain includes Sir Arbuthnot Lane, Sir Humphry Rolleston, Sir John Bland-Sutton, Sir John MacAlister, and Mr. Philip Franklin, whilst the similar committee in the United States consists of such well-known physicians and surgeons as Dr. George W. Crile (nominated by the American Academy of Science on International Relations), Dr. W. J. Mayo and Dr. Charles H. Mayo, of Rochester; Dr. A. H. Ochsner, of Chicago; Dr. Rudolph Matas, of New Orleans; and Dr. Franklin Martin, of Chicago.

The organisation of the American Hospital is thus becoming of considerable international value, whilst in science it presents possibilities which have scarcely yet been fully realised. Nor is the social side being disregarded. In July the authorities of the hospital will entertain at dinner one of its American colleagues, Dr. Charles Mayo, whose surgical clinic at Rochester, Minn., is known wherever medical men congregate together.

THE STERILISATION OF MILK BY ELECTRICITY.

IN THE LANCET of May 9th, 1914, we reported the findings of some interesting investigations carried out in the Thompson Yates laboratories in connexion with the possibility of sterilising milk by electrical treatment. The work was undertaken by the professor of bacteriology in the University of Liverpool, Dr. J. Martin Beattie, and the results were of a promising character. A further quest, interrupted by the great crisis, has since been made and the Medical Research Committee has issued this week a report[1] by Professor Beattie, which presents the practical details of the method so far as recent work has developed. At the outset it was decided to refer the question to Professor R. F. C. Leith, of Birmingham University, with the result that he was able to confirm Professor Beattie's claim for the efficiency of the electrical method in sterilising infected milk. The conclusion now is that milk can be rendered free from *B. coli* and *B. tuberculosis* by the electrical method described, without raising the temperature higher than 63° or 64° C. The temperature effect is very short in duration, and in itself is not the principal factor in the destruction of the bacteria. It is stated that though the milk is not sterilised in the strict sense of the word, yet the percentage reduction of the bacteria, taken over a period of a fortnight, is 99·93. The keeping power of the milk appears to be increased, the taste is not altered, and, so far as careful chemical examination can determine, the properties not impaired. Finally, it is definitely stated that the milk so treated can be described accurately as raw milk free from pathogenetic bacteria. No very extensive work has been done nor safe conclusions deduced as to the biological value of the milk so treated, but so far babies fed on this milk are reported to have done "extremely well." The bactericidal effects are attributed not to the direct action of the current, as such, upon the bacilli, but to the heat generated in its passage, suggesting a thermal method of destruction. The opinion is expressed that in the electrical method the current raises the temperature of the milk more quickly than occurs in simple heat-sterilising, and since this current passes through every part of the milk the heat which it generates reaches the whole of the fluid at the same moment. We note that the electrodes used are made of copper, and it is known that traces of this metal serve a bactericidal purpose, but in the report it is stated that no trace of any copper or other metal could be found. The Medical Research Committee concludes that this work has presented us with "an elegant and practical method of purifying milk for human consumption, of which the use upon a large scale becomes now a problem for closer financial and administrative examination." The economic aspect of the question is not referred to in the report, but, if this should raise no difficulty, it will remain to ensure that the adoption of the method leads to no discouragement of clean methods in the byre and dairy.

BREATH-HOLDING AS A CRITERION OF CARDIAC EFFICIENCY.

IT is nearly two centuries since Valsalva's classic experiment in 1740 showed the marked and easily recognisable effect of sustained forced expiration on the pulse-beat, and therefore on cardiac efficiency, when the respiratory passages are forcibly closed. A hundred years later, in 1838, Johannes Müller, of Berlin, added the complementary experiment of the effects on the pulse of forced inspiration under similar conditions. These two experiments have become classic, and suffice to demonstrate the intimate relationship between respiratory movements and cardiac efficiency, which has since been studied in many bearings. A direct practical application of the value of these facts was set forth in our issue of last week (p. 976) in dealing with the testing of the fitness of would-be airmen for their trying avocation. The tests are relatively simple, easily applied, and enable the physician to ascertain the condition of the lungs, to measure—by a mercury manometer—the force of the expiratory muscular mechanism, and the pulse response under varied respiratory conditions. The breath-holding test enables the physician to obtain a fair idea as to the stability of the central respiratory nervous apparatus of the examinee. A stop-watch and a nose-clip are all the apparatus required, while the precise instructions as to carrying out the experiment are equally simple. The time the man can hold his breath before the inevitable and forceful sensation of the need to breathe compels him to give way is noted. The average time in the normal fit pilot is 69 seconds, the minimum being 45 seconds. Nearly all cases with a time record as short as this were rejected on medical grounds apart from this test. Not the least interesting part of the test as applied to airmen is the reply given when the examinee is asked what caused him to give way and breathe in, the normal response being, "I had to give up," or "I wanted to breathe." Under conditions that point to unfitness for pilotage the reply may be, "I felt giddy" or "dizzy" or "squeamish" or "flushed," responses which indicate that other nerve centres are involved besides the true bulbar respiratory centre. Such extraneous sensations, so markedly different in character from the pure inspiratory impulses, enable the observer to form conclusions, not only as to the stability of the respiratory centre itself, but indirectly of those other parts of the central nervous system whose stability plays an important part in the nervous outfit of the aeronaut. The combination of minimum time record and abnormal verbal response points to the examinee being one likely to suffer from oxygen hunger at high altitudes, and possibly to an inherent inability, by a strong effort of will, to carry on under conditions of stress. The breath-holding test may have a similar application in other branches of medical practice. It was effectively used by Dr. H. F. Marris in an attempt to estimate the factors in the production of tachycardia occurring in febrile illness, printed with a series of admirable charts in our columns on May 11th, 1918. The general practitioner might add it to his armamentarium.

CONTUSION OF THE PELVIS A CAUSE OF RETENTION OF URINE IN CASES OF ENLARGED PROSTATE.

IN the *Gazette Hebdomadaire des Sciences Médicales de Bordeaux* M. E. Loumeau has called attention to a cause of retention of urine in cases of enlarged prostate which does not seem to have been previously recognised—contusion of the pelvis. It is generally said that the onset of acute retention, the attack of prostatic congestion, as Legueu terms it, is usually due to exposure to cold, undue postponement of the need to micturate, change of regimen (excess of alcohol, diuretics, spices, &c.), sexual excitement, constipation, an attack of piles, shocks to the perineum from the vibrations of railway trains or badly sprung vehicles, or immoderate horse or bicycle exercise. But M. Loumeau has found that a sudden contusion of the perineum, whether directly by a fall on the buttocks, sacrum, or coccyx, or indirectly by a fall on the feet may bring about the same result. In his practice as a genito-urinary surgeon he has met with 15 such cases. The following are examples:—

A man, aged 51 years, who suffered from frequency of micturition at night, fell on his coccyx. Retention of urine followed, but disappeared after single use of the catheter. Seven years later, after a railway journey, he had another attack of retention, for which catheterism was very difficult. He was cured by prostatectomy.

In a second case a man, aged 63 years, had suffered for a long time from frequency of micturition by day and night. He was struck by the shaft of a cart and thrown, falling on the posterior surface of his pelvis. Complete retention of urine followed and lasted for four weeks, during which he was catheterised several times a day.

In a third case a man, aged 67 years, who had never had any urinary trouble, was knocked down by an automobile, which struck him on the chest and threw him violently on the posterior surface of the pelvis. Several ribs were broken. Complete retention of urine with incessant attempts at micturition followed. After prolonged effort clear urine was passed involuntarily drop by drop almost continuously, and there was intolerable pain in the lower abdomen. Bronchitis, œdema of the face and legs, and a generally miserable condition ensued. He was treated in hospital only for the fractured ribs, and was not seen by M. Loumeau until nearly three months after the accident. There was a greatly enlarged prostate with incomplete aseptic retention of urine and micturition by overflow. The bladder could be emptied only by a greatly curved metal catheter because of the prostatic obstruction. Suprapubic cystotomy was performed and showed enormous dilatation of the bladder. In consequence of the general condition of the patient prostatectomy was not performed until a week later. He was then completely cured.

In such cases the retention is evidently due to acute congestion of an already adenomatous prostate brought about by the injury. This retention may be the first symptom of old hypertrophy of the prostate, until then "silent" and unsuspected. The complication of contusion of the pelvis is of medico-legal importance, as it is a responsibility of the author of the accident.

MEDICAL REMEDIES: SAFEGUARDS FOR DOCTORS AND PUBLIC.

THE Ministry of Health calls attention, under this heading, to the misunderstandings which have arisen as to the objects and scope of the Committee recently appointed by Dr. Addison to consider measures for the effective control of certain therapeutic substances. The official statement is as follows:—

> The terms of reference do not include and have no relation whatever with the subject of patent or proprietary medicines (as those terms are popularly understood), nor is the work of the new Committee in any sense a reduplication of the work of the Select Committee on Patent Medicines appointed in 1912.
>
> The "therapeutic substances" now under consideration are recognised remedial substances, the purity and standard of efficacy of which cannot be adequately ascertained by the employment of ordinary chemical tests as can that of the great majority of medicinal substances. This determination can only be done in the substances under consideration in properly equipped laboratories by the employment of biological or physiological methods. The substances in question may be divided into two great classes: (1) bodies such as serums and vaccines, of which a well-known example is the antitoxin given in cases of diphtheria; (2) mineral and vegetable bodies of another kind, the most familiar examples of which are salvarsan, the well-known remedy for syphilis, and digitalis, a remedy in certain forms of heart disease.
>
> At present there is not in this country, as there is in some others, any effective supervision and control of the manufacture or standardisation of many of the important agents mentioned above. The work of the Committee is, among other things, to devise measures to coördinate and control the various tests and standards employed by firms and persons engaged in the preparation and sale of these substances, and to devise a uniform system of standardisation and control the better to guarantee that these agents are what they purport to be and are of an accepted standard of efficacy.
>
> In a few cases, however—e.g., salvarsan—a body of the nature defined above may be the subject of a patent. It is only in such exceptional products, which are usually of foreign origin, that the question of patent medicines will arise at all, and even these bodies have nothing whatever in common with the ordinary run of patent and proprietary medicines with which the public is familiar.

In our issue of May 1st we informed our readers correctly as to the objects of the new Committee. The careless interpretation put upon these objects by some of the lay, and even some of the medical, papers has caused considerable misunderstanding.

In this connexion it is interesting to refer to a paper published in the April number of the *Journal of the Chemical Society*, just issued, in which it is shown that the composition of salvarsan is variable. This statement is significant since obviously any departure from a normal structure may well disturb therapeutical expectancy. The authors, Robert George Fargher and Frank Lee Pyman, state that when salvarsan was first introduced into general use the makers, a well-known German firm, claimed that salvarsan as made by them contained about 34 per cent. of arsenic. In 1911, however, it was reported by a writer in the *Apoth. Zeit.* that the substance lost 7·6 per cent. of its weight on heating and contained only 31·2 or 31·8 per cent. of arsenic. These results were communicated to Ehrlich, and later the makers issued a corrected statement in a circular to the effect that "the arsenic content of the preparation corresponds to the formula—$C_{12}H_{12}O_2N_2As_2 2HCl 2H_2O$" (=31·6 per cent. As). Later Ehrlich and Bertheim put forward the view that the final substance contained a methyl group, and Kober claimed the absence of $2H_2O$, and expressed the opinion that the combined solvent in salvarsan, precipitated from methyl alcohol by means of ether, is methyl alcohol. On seemingly good grounds Fargher and Pyman show that this view is erroneous, though they note that when salvarsan is precipitated from methyl alcohol solution, by means of acetone instead of ether, the product contains a molecular proportion of acetone in more or less stable combination. They point out also the presence of a considerable proportion of sulphur in commercial salvarsan, which was not disclosed in the reputed formula. The authors consider that the sulphur occurs, at least in part, in the form of the sulphamo group. A series of analytical figures shows distinct variations in sulphur, chlorine, and other contents in ten preparations examined. The authors describe a process for isolating a pure product. The call for standardisation is obviously clear.

THE SURGICAL TREATMENT OF PROLAPSE OF THE UTERUS AND VAGINA.

Dr. Blair Bell's lecture on this subject, delivered last Wednesday before the Royal Society of Medicine and published in this issue of THE LANCET, deserves the careful study of gynæcological surgeons. The after-results of his operations (99 per cent. of cures in 4000 cases) are so good that we welcome his contribution to the subject. He rightly emphasises that "no one procedure is suitable or satisfactory for every type of case." Cases of prolapse of the uterus and vagina are divided into two main groups by the writer, and the surgical treatment adopted differs in the two groups. The first group consists of cases of prolapse during the reproductive period, and the author at the outset condemns the operation of ventrifixation, and considers ventro-suspension useless. He advises repair of the vagina and perineum, amputation or repair of the cervix, if necessary, and his modification of Gilliam's operation to suspend the uterus. In bad cases more is required, and Dr. Blair Bell commends reconstruction of the peritoneal aspect of the posterior segment of the pelvic floor. By this method the pouch of Douglas is obliterated, with the result that this part of the pelvic floor is greatly strengthened. The second group of cases consists of those occurring at or after the menopause, and for these he favours the interposition operation, together with properly performed vaginal repair, although if there is no descent of the uterus the latter alone will suffice. Dr. Blair Bell attributes failure of the interposition operation to sepsis, and his experience of this operation has been far happier than that of most operators. It is evident that this operation will have to be reconsidered in the treatment of prolapse, and we have no doubt that considerable discussion will arise upon its merits in uterine prolapse. The principles enunciated with regard to vaginal repair are now well established, and most operators of experience will agree with them. Dr. Blair Bell rightly lays great stress on the preparation and after-treatment of his cases, and we agree that skilful nursing is essential for the ultimate success of the operation.

THE TRAINING OF BLIND STUDENTS.

AN important memorandum has been issued by the Board of Education, who consider that the time has now come when some further endeavour should be made to secure provision of better and more extended facilities for students formerly in attendance at special schools, and in especial for training blind students. With this end in view, they have decided to modify and substantially to increase their grants in aid to training institutions. The primary object is to provide an essential link between the special school which provides primary education up till the age of 16 and the workshop; but provision is also to be made for the needs of blind persons who, owing to the age at which they became blind or other circumstances, have not attended a special school, but who are capable of benefiting by attendance at a course of training. In determining the trades for which instruction and training can best be provided, the Board advise that careful consideration be given to probable openings for employment, either in the field of professional employment or in the open markets of industry and commerce, locally or otherwise, or in special workshops, or in home industries. To meet the needs of these students they recognise that a large proportion of them can only be provided for in residential institutions, and by offering largely to increase the grants it is hoped to enlist the more active coöperation of local education authorities. The new regulations in the first place provide for the payment to a local education authority of a grant of one-half of the net expenditure on: (*a*) approved courses at recognised institutions provided by the authority, and (*b*) payment of fees of students attending approved courses at a recognised institution not provided by the authority. Secondly, it has been decided to continue to pay grants direct to an institution not provided by an authority in respect of students for whom no fee has been paid by an authority, and to increase these grants to a maximum of £8 10*s.* a year, with an additional £8 a year for any student who is resident in the institution. These grants will be retrospective so far as the financial year commencing April 1st, 1919, is concerned.

VISIBLE GROWTH.

GARDENERS and reformers have this in common that they would both like to see their work grow beneath their eyes. Hitherto they have had to rest content with inferring growth from the fact that the objects of their care appear longer or broader after an interval of days or weeks. Even the gourd, which grows up in a night, shows no change to the most watchful eye. Under the microscope some of the lower forms of life may seem almost to grow, the pullulation of yeast cells being a familiar example. It is, of course, only a question of magnification and accuracy of perception. Continuous growth is there, if we were only able to perceive it. To Sir Jagadis Bose we owe the demonstration of the growth in the higher forms of vegetable life within a period of minutes. His crescograph, brought to perfection after years of painstaking study in the Research Institute which he founded at Calcutta, exaggerates the motion of the growing tip of the vegetable shoot a million times or more, rendering it plainly visible to a roomful of ordinary people possessed of no special powers of observation. Obviously accidental movement, due to warmth or other physical factors, similarly exaggerated by enormous magnification, has to be reckoned with. But Sir J. C. Bose was able a few days ago to satisfy six London professors of exact sciences of the actuality of the growth by means of apparatus set up in the physiological laboratory of University College, London. Each step in the process of growth became visible. The inventor has used his instrument himself to show the stimulating effect of sunshine and the depressing effect of ether on vegetable growth. Thus a physical reagent has been found for the presence of life in a body, and the vividness of that life under various experimental conditions can now be assessed in terms of linear measurement. The discovery may enable us to get nearer to the knowledge, which we so ardently desire, of the nature of life itself.

ROYAL ACADEMY EXHIBITION.

THE 152nd exhibition of the Royal Academy appears to have received from critical pens a favourable endorsement. Speaking only for a limited section of the public we are not surprised. The exhibition marks, in our opinion, real progress, not so much in technique—concerning which we have no qualification to speak—as in the qualities which so many of the pictures possess. Numerous as the exhibits are it is an open secret that they are the result of arduous selection among many competing canvases. If there are a good many efforts on the walls which might have well remained outside the show, many of these only fail because other examples are better, and there is a far lower percentage of the quite commonplace picture deliberately painted to meet what is supposed to be public demand. The fact is that public taste has been considerably educated of late, and it is possible that the general upheaval of social circumstances produced by the war has compelled a large number of people, for the first time in their lives, to look at the world in which they live, and thus to see things as they are and not as they think they should be. This is undoubtedly exactly what has happened with therapeutics, and it is natural that it should occur also in the world of art. There are few paintings of particular medical interest, and we do not observe any story pictures depending for their appeal upon what the artist considers to be the pathetic or dramatic side of medical work. We welcome with emphasis the disappearance of this kind of picture. Of well-known artists, Mr. Sargent is a notable absentee. Sir William Orpen, Sir John Lavery, and Mr. Clausen lend particular distinction to a very satisfactory exhibition. To Sir William Orpen's beautiful and dignified presentation portrait of Sir Clifford

Allbutt we referred last week. It hangs in the first gallery, and is certainly one of the pictures of the year.

COUNCIL OF BRITISH OPHTHALMOLOGISTS: A RETROSPECT OF TWO YEARS' WORK.

THE Council of British Ophthalmologists was founded at a meeting held at the Royal Society of Medicine on May 2nd, 1918. It owed its inception to the need for some body which could act rapidly and authoritatively in regard to questions of ophthalmological interest arising in connexion with national industries or public services. In the past such questions had usually been referred, often in a haphazard manner, to individual ophthalmic surgeons, who could express only their own opinions. Fortunately, many of those to whom application was made were well fitted to give advice, but a consensus of feeling arose that such advice would be of more value if given after the subject had been considered by a council representative of the general body of British ophthalmic surgeons.

During its two years of work the Council has found ample justification for its existence, as is sufficiently shown in the report presented at a meeting of British ophthalmic surgeons held at the Royal Society of Medicine on April 30th. Four communications have been published, dealing with (1) Standard Illumination of Tests of Visual Acuity; (2) The Need for Improved Training of Medical Students in Ophthalmology; (3) The Need for a Higher Qualification in Ophthalmology; (4) Vision of Men Engaged in Motor Road Transport. In regard to the second the report expresses regret that the General Medical Council has not yet taken effective action to remedy the deficiency. The third has already exerted a valuable influence. The Council has had the satisfaction of seeing the general conclusions reached in regard to the vision of motor drivers adopted by the police authorities in London and elsewhere, and finding acceptance with the leaders of the men concerned. These published communications represent only a part of the work of the Council. Four members were nominated to serve on a London County Council committee dealing with the lighting of cinemas and eye-strain. Committees are considering the standardisation of test types, the notation of cylinder axes, and the question of sight-testing by opticians. Two representatives are serving on the Advisory Committee on Technical Optics. The report closes with the brief remark that the expenses of the Council have been defrayed by its members.

POST-GRADUATE STUDIES IN BRISTOL.—The Director of Post-graduate Studies in the University of Bristol announces a course of demonstrations for Wednesday afternoons during May and June alternately at the Royal Infirmary and General Hospital. The subjects are as follows: May 12th, Medical Cases; May 19th, Atonic Dilatation of the Stomach, by Professor P. H. Edgeworth; May 26th, the Causes of Indigestion, by Dr. Carey Coombs; June 2nd, Recent Physiology and Surgical Pathology of the Stomach, by Mr. Rendle Short; June 9th, Surgery of Gastric Ulcer and Pain, by Mr. T. Carwardine; June 16th, Cutaneous Reactions in Asthma, Urticaria, and Idiopathic Vomiting, by Dr. J. A. Nixon; June 23rd, Treatment of Simple Fractures by Extension Appliances, by Mr. Hey Groves; June 30th, Surgical Cases. A fee of 2 guineas covers this course, as well as one month's attendance at any or all of the clinical departments of the University. Opportunities of daily study are also afforded to clinical assistants, who, in addition to work in particular departments, are made free of laboratories, library, and so on, at a rate of 3 guineas per month. All inquiries should be addressed to the Director of Post-graduate Studies (Clinical Section), Pathological Department, University of Bristol.

KING EDWARD'S HOSPITAL FUND FOR LONDON.

IN order that the hospitals of London may immediately benefit by the funds collected under the auspices of King Edward's Hospital Fund for London a preliminary meeting is held at the end of the year, when the report of the Distribution Committee is announced and the awards allocated. An account of the last meeting was published in THE LANCET for Jan. 3rd (p. 50). The annual meeting was held at St. James's Palace on April 30th, when the Earl of Donoughmore presided. At the commencement of the proceedings a resolution of regret was carried in silence on the announcement of the death of Sir Henry Burdett, who, in many ways, was, as Lord Somerleyton pointed out, the originator of the idea of the Fund. In presenting the account of receipts and expenditure for the year ending Dec. 31st, 1919, Lord Revelstoke, the honorary treasurer, reminded the Council that in order to meet the cost of renewals and repairs of hospitals, deferred owing to the war, it was estimated that £50,000 would have to be drawn from reserves, but this had proved an over-estimate by £4000. The motion, on the proposal of Lord Donoughmore, seconded by Sir T. Vesey Strong, was carried unanimously. Sir Frederick M. Fry, honorary secretary, submitted the draft report of the Council, which showed that the total receipts for the year 1919 were £201,477 0*s.* 9*d.*, of which £8422 2*s.* 2*d.* were contributions to capital, and £193,054 18*s.* 7*d.* receipts on general account.

The General Fund receipts were made up as follow: Annual subscriptions, £25,199 13*s.* 2*d.*; donations, £7143 7*s.* 3*d.*; League of Mercy, £17,000; legacies, £21,976 2*s.* 8*d.*; dividends and interest from investments, £116,535 15*s.* 6*d.*; trustees of the Bawden Fund, £200; estate of Samuel Lewis, deceased, £5000, making a total of £193,054 18*s.* 7*d.*

During the year the amount spent on the administration of the Fund was £4085 17*s.* 9*d.*, or £2 0*s.* 6*d.* per £100 of the total received, as compared with £3672 19*s.* 2*d.*, or £1 13*s.* 7*d.* per £100 in the previous year. The average yearly outlay in this respect for the whole period since the inauguration of the Fund has been £2954, the corresponding percentage of the receipts being £1 5*s.* 5*d.*, or less than 3¼*d.* in every £1 received.

The question of hospital extensions has for some time been engaging the special attention of the Distribution Committee. By the end of 1917 schemes had been notified which, if they were all carried out, would have the effect of adding 1750 to the number of beds available in 1913. By the end of 1918 the number of additional beds provided and contemplated amounted to about 4000, of which about 1000 had already been opened since 1913, and the Distribution Committee had begun a detailed examination of all these schemes, partly in connexion with the pending special distribution of surplus Red Cross funds, and partly for the general purpose of securing that no scheme should be undertaken without due regard to financial practicability, and to the general effect of all the schemes taken together.

The Council are under great obligations to the newspaper press for the assistance they have rendered in the past, and continue to rely upon their kindly coöperation in obtaining for the Fund wider publicity and support. Their help is more than ever valuable at a time like the present, when hospital expenditure has enormously increased, when the subscribing power of many regular contributors has diminished, and when, therefore, it becomes more and more important that the special value of the work of the voluntary hospitals, and their claims to increased support, should be brought home to a wider public.

In moving the adoption of the report, Lord Donoughmore referred to an estimate recently issued by the honorary secretaries of the Fund in which it was shown that the total expenditure of the London hospitals in 1919, taken together, amounted to £2,100,000. Towards this their income, including the grants from the three central funds, amounted to about £1,900,000, leaving a deficit on the year's working of £200,000, or approximately 10 per cent. The annual deficit of the London hospitals at the time of the inauguration of the King's Fund in 1897 was about £70,000, which, by a coincidence, was also about 10 per cent. of the expenditure. Although during these 23 years the hospitals had been able to pay their way, the income increasing with the expenditure, it was not wise to be too optimistic of the future. The present difficulties of hospitals were not the result of any failure on their part, but arose solely from the general financial effects of the war. The motion was seconded by Mr. Norman, Governor of the Bank of England, and carried. A vote of thanks to Lord Donoughmore terminated the proceedings.

HOUSING NOTES.

Housing Bonds Campaign.

THE campaign for raising local funds to support the housing schemes already in progress was inaugurated at the Guildhall on May 3rd. In the absence of the Prime Minister, which was due to sickness, Mr. Bonar Law appealed to a large audience of city men and delegates from local authorities. He pointed out that while in matters of social reform the country must have regard to the capital at its disposal, the credit of the country was itself dependent upon the stability of industrial conditions; a sullen and angry populace might be fatal to the industry and credit of the country. The same point was made in a letter from the Prime Minister, who wrote that "adequate housing would ensure happy homes, which are the surest guarantee any country can provide against agitation and unrest."

Mr. Law touched on the impossibility of securing such homes under present conditions, and said that the attempt to stamp out tuberculosis was hopeless while overcrowding persisted. The five years' arrears of housing would not be made up without an exceptional effort. This effort was being put forward by the Government. On upwards of 30,000 houses work was actually in progress, and a stage had now been reached when the programme was in danger of interruption for want of financial guarantees. Every class of the community should assist, since every class was interested. He appealed in particular to employers of labour and to the churches. Many industries, though they needed more men, were unable to absorb those who were out of work because no houses could be found for them to live in. Religious bodies must realise that the moral and spiritual well-being of the people was bound up with housing conditions.

Dr. Addison, in proposing a vote of thanks to Mr. Law, announced that 40,000 to 50,000 houses were held up because local authorities hesitated to sign contracts. The contracts now prepared were sufficient, he said, to employ nearly the whole of the building trade. To an interrupter, who wished the State to furnish all the necessary funds, Dr. Addison retorted that each locality had its own problems and responsibilities. The State could only get money from its citizens, and the people of each locality must be moved by a sense of duty to those amongst them who had fought in the war and now are homeless.

Mr. Walter Leaf, the President of the Institute of Bankers, seconded the vote of thanks and promised the bankers' support in the campaign.

Though none of the speakers made any definite appeal to the profession, medical interest in the health of the community will certainly promote earnest endeavour.

Standards of House Construction.

While so many new houses are being put up it is important that a reasonable standard of construction shall not be sacrificed to the urgency of the moment. An official of the Ministry of Health, who resigned recently, gave as one of the principal reasons for his resignation his opinion that the standards laid down in the Housing Manual are not being maintained in practice. Dr. Ira S. Wile raised some interesting points in this connexion in a paper read last autumn to the Sociological Section of the American Public Health Association.[1] In one city (Johnstown, Pa.) the infant mortality-rate in homes with bath-tubs was 72·6 and without 164·8. The effect of overcrowding both on infant mortality and on various contagious diseases is also discussed in this paper. Among the methods advocated by Dr. Wile for raising the standard of house construction are: "the education of the public as to the natural value and importance of sanitary dwellings; ...... the promulgation of minimum standards of housing construction, and particularly the regulation of standards of maintenance and repair; ...... the support by health departments of those measures tending to increase family incomes, so as to bring about a minimum standard of living wage." Lord Astor, speaking recently to a Conference of the National Council of Public Morals, said that unless we swept away slums, slums would sweep away the existing order of society, from which it may be gathered that the official view of housing standards is certainly above the practice of East London, whatever may be said of the new houses in the north.

The Limit in Overcrowding.

Reports from all parts of the country confirm the impression that the population is becoming more crowded and harassed for want of houses as the months of peace are multiplied. At Yeovil the relieving officer told his board of guardians on April 16th that there was a family living in a farm out-house. They had been ejected from their home. At Shoreditch the coroner was properly shocked to hear of a man sleeping in one bed with two of his daughters, one of them 19 years old; but it appeared that the family of five lived in a two-room tenement and slept in one room containing two beds. As the mother and one child were seriously ill with influenza the conventions could hardly be respected. Under such conditions, if one member of the family catches any infectious disease it is almost inevitable that all should suffer and no one be left to nurse the sick.

The Need for Public Interest.

In face of such stories as these, the difficulties still to be overcome by the Ministry of Health are almost incredible. The shortage of labour remains a most serious obstruction, and though the least wealthy are certainly the worst sufferers through the present state of affairs, it seems impossible to move the building unions to admit "diluted" labour. So serious is the result that it becomes a duty incumbent upon every public-minded citizen to support the local authorities in his own neighbourhood and to put his private purse no less than the stimulation of his personal interest at the service of whatever schemes may be in hand. It may be well to remind those who find little sympathy with public schemes that the Government bonus is payable to all who build houses through private enterprise so long as these houses are completed by Dec. 23rd, 1920. The plans have to be approved by the local authority. The General Housing Memorandum No. 25, issued by the Ministry of Health in March, gives full particulars, while a White Paper[2] issued in the same month gives the specifications required by the Ministry for wooden houses. This is of interest in view of the short time allowed for completion of the building. The bonus on the first two completed houses has already been paid.

Housing Reform in South Africa.

In South Africa the disgraceful condition of the poorer dwellings in many of the large towns was brought to light by the severe influenza epidemic of 1918–19. Hottentots, Kaffirs, and Whites too, were found living in insanitary, ill-ventilated, and badly overcrowded dwellings. The shortage of houses made immediate reform the more difficult to accomplish, but although the South African Government has so far taken no steps, many municipalities have undertaken local housing schemes, and others are discussing the advisability of so doing. Bloemfontein is generally considered to be the model city in this respect. Here the municipality have built a quarter of ideal workmen's cottages and insist that the workers shall be able to keep the cottages in good order and to pay an "economic rent." To this end every worker must earn at least 7*s.* 6*d.* daily. If his trade cannot pay him at this rate he is allowed an allotment for cultivation in his spare time, so that the deficiency in his regular wages may be made up. Here is an object lesson which some of our own local authorities might do well to study.

THE MEDICAL EXAMINATION OF THE CIVILIAN AERONAUT.[1]

(Concluded from p. 976.)

The methods employed in the medical examination of civilian pilots, navigators, and engineers were set out briefly, though substantially in the words of the official publication, in these columns last week, but only the general medical and surgical standards required were commented upon. It is, of course, essential that the candidate, when his general health conditions have been found to fit him for his occupation, should also be in full possession of his special faculties of seeing, hearing, and that the vestibular apparatus, the nose, throat, and buccal cavity, should be normally formed and fit to discharge their physiological functions.

As the Report points out, the importance of a reasonable degree of visual acuity is obvious, but ability to judge distances is an even greater necessity. Normal refraction and a healthy condition of retina and intrinsic muscles is required for the first, while for the second it is necessary that the aeronaut should possess good binocular vision and normal balance of the extrinsic muscles. The scheme of the medical examination is set out as follows:—

Eye Examination.

Both intrinsic and extrinsic muscles are liable to a lack of tone or over-action. Occurring with intrinsic muscles, visual acuity is directly affected. With intrinsic muscles lack of tone and over-action are not only liable to affect visual acuity, but also tend to give conflicting, delayed, or wrong interpretation of messages sent from the eye to the brain, and the ensuing reactions will, in consequence, tend to be delayed or even at fault. When, therefore, these conditions exist danger to life and material is obvious, and one of the most important aims of the eye examination should be their early recognition.

Examination of the muscular balance and its defects is extremely difficult, and full of pitfalls; it must be remembered that fusion faculty is largely dependent on physical health and that any slight fault may be exaggerated by entirely temporary causes such as fatigue, illness or recent application at close work, especially if there has been acquired a habit of suppression or neglect of one or other eye.

The Royal Air Force are at present only admitting candidates with an unaided visual acuity equivalent to 6/6 in both eyes. Provided that heterophoria is absent, or only present to a slight degree, in certain specially suitable cases this visual standard may be slightly relaxed for civilian aviators. It is, however, not advisable to allow the standard (even in special cases) to be below 6/9 and 6/12, correctable to 6/6 with glasses.

Cover test for muscular defect.—Ask the patient to fix a pencil in a similar manner, and with the other hand cover one eye with a card and then uncover; watch whether the eye moves on uncovering. Repeat the test for the other eye in a similar manner. A perfectly balanced pair of eyes will remain fixed on the pencil whether one is covered or not, whereas movement inwards or outwards on uncovering shows lack of balance under convergence.

It is evident that the medical man conducting an eye examination of this quality must be considerably familiar with his subject, as the tests are of a high physiological standard, but it is provided that doubtful cases can be referred for examination by a specialist. With regard to the difficult subject of colour vision, it is notorious that there are differences of opinion in respect of the Board of Trade standards and existing regulations for master mariners and engine-drivers. Dr. F. W. Edridge-Green, by work of the highest physiological quality extending over many years, has been able to show that more than half the colour-blind persons can pass the Holmgren wool tests, tests which, moreover, may lead to the rejection of candidates with normal colour vision. In consequence, Dr. Edridge-Green's lantern has been adopted by the Navy for the standardisation of colour perception, a reform which ought soon to take place in the regulations of the Board of Trade, by which the examinations of the civilian aeronaut are guided.

Ear Examination and Vestibular Apparatus.

With regard to the vestibular apparatus, the value of routine examinations by the various Barany tests has not been finally accepted by the Royal Air Force, further investigation having been undertaken into the records which have been kept. A reference is given in the selected bibliography (attached to the pamphlet) of the printed work in this direction which has been published in the United States, where great importance is attached to the Barany tests.

The following are the directions for the examination or re-examination of candidates, to see that they possess hearing sufficiently acute to detect accurately signals and ascertaining minor defects in engines.

(i.) *Hearing.*—The hearing in either ear must be acute, that is, equivalent to a forced whisper at a minimum distance of 20 feet, each ear being tested separately with the meatus of the other side occluded and the face turned away. In cases of failure, when it is considered that treatment may bring the hearing up to standard, the subject may be temporarily deferred and re-examined at a later date.

(ii.) *External ear meatus and membranes.*—(Apparatus required: usual ear examining instruments.) *(a)* Meatal infections and obstructions, while not permanently disqualifying, must be satisfactorily cured or removed before acceptance. *(b)* A permanent dry perforation in the membrane constitutes a disqualification for air work. *(c)* Cicatrices of the drum of long standing, unless obviously liable to breakdown under alterations of atmospheric pressure, may be passed, provided that the hearing is up to standard and that there is no cause in the nose, pharynx, or naso-pharynx for reinfection.

(iii.) *Middle ear and Eustachian tubes.*—*(a)* Catarrhal or suppurative otitis media. If the condition is acute or subacute the applicant or airman should then be referred for treatment and subsequently re-examined. Chronic suppurative otitis media is a cause for rejection, as also the radical mastoid operation, successful or otherwise. A healed operation for acute mastoid suppuration, with satisfactory hearing and a sound membrana tympani, need not be considered a cause for rejection. *(b)* Oto-sclerosis should constitute a cause for rejection. *(c)* The examiner should satisfy himself that both Eustachian tubes are patent, and should reject cases of permanent obstruction, but not temporary ones.

(iv.) *Cochlear apparatus.*—"Nerve deafness" or any other disability of the cochlea or cochlea nerve tract should not be present. Applicants or airmen suffering from affections of the internal ear, accompanied by deafness or labyrinthine symptoms, should not be accepted for air work.

Examination of Nose, Throat, and Buccal Cavity.

The Report points out that anything tending to block the upper respiratory passages by interfering with the ventilation of the lungs constitutes a great disability for the carrying out of any duties in the air; and under this heading the wise precaution is added that symptoms, apparently trifling in importance on the ground, may be considerably aggravated in the air. While the medical examiner must bear this in mind in estimating the circumstances of the ears, nose, and throat, he is wisely enjoined to give due weight to the previous flying history. If a candidate has shown no disability in these directions when flying, the absolute evidence in his favour is to be considered before negative evidence resting on presumption. The instructions run as follows:—

(i.) *Buccal cavity.*—Carious teeth, gingivitis, and pyorrhœa must be successfully treated before acceptance. Artificial teeth do not disqualify, but care must be taken that the plates are well fitting.

(ii.) *Pharynx.*—Tonsils. *(a)* Enlarged tonsils which produce obstruction, or which become repeatedly inflamed or associated with attacks of quinzy, must be enucleated before an applicant can be accepted. *(b)* Septic tonsils, even only unhealthy remnants, from which the septic material can be expressed, or which cause repeated sore throats or chronic enlargement of the glands of the neck, must be enucleated.

(iii.) *Naso-pharynx.*—Adenoids, however small in amount, when causing repeated colds, with acute or subacute Eustachian obstruction, or catarrhal or suppurative inflammation of the middle ear, should be removed before an applicant is accepted.

(iv.) *Nose.*—*(a)* Mouth-breathing constitutes a serious flying disability. *(b)* Deviated septum. If this blocks more than half the air-way in one nostril, or is associated with frequent colds or headaches, it should be remedied by operation before the applicant's acceptance. Slighter degrees may be ignored. *(c)* Turbinal hypertrophy should also be remedied by treatment before an applicant is accepted. *(d)* Infection of the accessory sinuses. Acute infection must be cured before accepting an applicant. Chronic suppuration constitutes a cause for rejection. If the antra alone have been affected, and a satisfactory operation has been performed leaving a free opening into the inferior meatus, and the subject is, in addition, free from all signs or symptoms, he may be accepted. Permanent drainage into the mouth should not be regarded as a satisfactory operation. *(e)* Nasal polypi must be removed and the cause cured before acceptance. *(f)* Atrophic rhinitis should constitute a disqualification.

(v.) *Larynx.*- Should hoarseness or any symptom or sign pointing to a laryngeal affection be present, a careful examination of this portion of the upper respiratory tract should be made.

A Valuable Report.

This able Report has been drawn up for the Royal Air Force by Lieutenant-Colonel C. B. Heald, medical adviser to the Civil Aviation Department, and is founded on a confidential document, written earlier by Mr. A. H. Cheatle, Dr. G. A. Sutherland Colonel H. C. T. Langdon, and Colonel Heald himself, later elaborated by Colonel Martin Flack, the valuable papers in our columns by the last named indicate his share in forming the Report It remains to congratulate Colonel Heald, and all who helped him, upon a straightforward and informing guide to the physical examination of the civilian aeronaut, and it may be added that the instructions will be very useful for the grading of any persons who are candidates for employment in positions of trust where industrial fatigue will play a part

PELLAGRA IN EGYPT IN 1918

REPORT OF THE COMMITTEE OF INQUIRY

IN 1918 there were many prisoners of war in Egypt, amongst whom a disease appeared soon recognised as pellagra, the number of cases growing till it became serious On Oct 6th, 1918, a Committee was appointed, under Colonel F D Boyd, to examine the situation and to advise how it should be met The report of the Committee, dated Dec 31st, 1918, has been appearing in the last five numbers of the *Journal of the R A M C*, and its conclusions are of great interest Not only did the Committee clear up the problem of pellagra in Egypt, but it has put on record observations that will have to be remembered by everyone who has in future to draw up any diet scale All medical officers who read this well arranged report will feel the importance of daily watching the condition of the rations supplied to their units and of paying attention to the work of the cooks, while the study of the Committee s clinical observations on pellagra will well repay the physician

Pellagra as it occurred in Egypt is a deficiency disease due to insufficient assimilation of protein and characterised by erythema and pigmentation of the exposed parts of the body (on the back of the hands first, a fortnight later the nose, later on the feet, these discoloured patches being dry and not sweating even under pilocarpine), this is followed by a profound disturbance of nutrition with early wasting of the muscles of the shoulder girdle, and progressively increasing fall in blood pressure Loss of appetite is a very early symptom and there is defective secretion of hydrochloric acid in the gastric juice Herewith there is impairment of digestion, both gastric and pancreatic, mal assimilation of both protein and fat, and an increased bacterial growth in the intestine, with intermittent diarrhœa leading to further loss of food ingested, but incompletely absorbed Also the enhanced destruction of proteids gives very foul smelling stools and indican appears in the urine in increasing quantities, apathy comes on, perhaps melancholia, and the patient dies The disease picture suggests suprarenal inadequacy, and, in fact, in the recorded cases the suprarenals averaged 15 gr lighter in the pellagra cases than in the controls There is no evidence of specific bacterial or protozoal infection Death is due to some intercurrent infection, pneumonia, dysentery, tuberculosis, or malaria accounted for 91 per cent of deaths The disease occurred in Turkish camps, not in the camps of Germans alongside, where there was money to buy extra food Spot maps showed that there was no infection from place or person

Preventive Measures

The important question was how this disease was to be prevented Investigation showed that 88 per cent of the cases had arisen amongst newly captured Turkish prisoners of war, who before capture had for months only had available two thirds of their normal ration, and had so suffered "from long continued under nutrition," as their German general had reported already the year before Further, the protein of their diet came mostly from wheat, barley, or maize, very little from meat Now Hopkins and Willcocks, in 1907, showed that the chief protein of maize cannot keep rats alive, as it does not contain enough tryptophane, an amino acid of the aromatic series, in 1913 Sandwith suggested that want of tryptophane might help to cause pellagra The Committee called in to help them Professor W. H Wilson, of the Cairo School of Medicine who has long been working at the different nutritional values of the proteins, which seem in part to depend on their individual amino acids For the making of adrenalin a benzene nucleus is essential For the production of this the human organism depends upon the hydrolysis of special proteins in the food supply, and even then the yield of tryptophane in this process may be broken up by an overwhelming bacterial flora in the duodenum Every diet scale considers how much protein is necessary for the man of 70 kg, which is agreed at 40 g daily But that means grammes absorbed, and for normal people must be increased by one tenth, but experiment proved that for Turkish prisoners it required to be increased by one half So that, even if they had got full rations, the Turks would have been underfed But, further, they were fed on the wrong proteins Professor Wilson had calculated the "biological value of the proteins" (B V P) of various foodstuffs and had found that, to replace 30 g of meat as protein supply in a man s diet, 54 g of rice protein were necessary, 50 of beans, 76 of bread, and 102 of maize And that is why maize eating people suffer proverbially from pellagra, it has the lowest B V P of all the cereals, and, of course, if it is damaged or decayed it is all the less nutritious and pellagra arises more quickly Vegetable proteins are not so easily assimilated as those in meat, and, further, the beans for the prisoners were not at first well cooked These difficulties were all adjusted, but it appeared that men might escape pellagra on a particular diet while they were resting, but succumbed as soon as they worked hard, so the diet for heavy labour, though showing already sufficient caloric value and vitamine content, had to be increased, then the pellagra ceased

Lieutenant Colonel P S Lelean and Professor H E Roaf have done excellent work is disentangling, with Colonel Boyd, a complicated problem

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

Hospital Finance in Aberdeen New and Successful Efforts

ON April 24th, when an excellent concert was given to a packed house in the Tivoli, the students of Aberdeen University completed a successful gala week on behalf of the finances of the Aberdeen Royal Infirmary The week commenced with a concert in the debating hall, Marischal College On the following day a football match was played between the University and the Aberdeen clubs, and a largely attended thé dansant was held in the Mitchell Hall On April 23rd students paraded all the principal streets in fancy dress with collecting boxes, and in the evening organised a torchlight procession The various events of the week were well advertised by a number of undergraduates who took their turn at parading the streets of the city as sandwichmen Women students took a prominent part The gala week was a new and most successful effort organised by the Students Representative Council, and it is to the work of the office bearers of that body that the excellent results are in large measure due The total sum collected was £1496 4*s* 11*d* and after meeting expenses of £21 13*s* 6*d*, there remains £1474 11*s* 5*d* to be handed over The successful efforts on the part of the students appear to have coincided with a widespread determination on the part of employers and employees of the large city firms to increase their responsibilities in the financing of the local hospitals The initiative has been taken by the workmen in the employment of Hall, Russell, Ltd, shipbuilders, who as the result of a ballot, have unanimously decided to double their annual contribution to the hospitals in the city The new subscription per man will be those earning £2 per week and under, 2*d* per month, those earning over £2 per week, 4*d* per month

University of Aberdeen Halls of Residence for Students

At a meeting of the Senatus of the University of Aberdeen held on April 28th, Principal Sir George Adam

Smith in the chair, a report by the special committee appointed to consider the question of halls of residence for students and other members of the University was approved in principle and forwarded to the Court. New regulations for the diploma in public health were also considered and forwarded to the Court.

Mother and Child Welfare Centre in Aberdeen.

The new Mother and Child Welfare Centre premises in the Castlegate, Aberdeen, were formally opened on April 30th. The building consists of a converted army hut, which contains a doctor's-room, weighing-room, a lecture hall for mothers, a provident-room, and a "toddlers' room," with an excellent shelter for the children leading on to a spacious playground, which is situated so as to obtain plenty of sunshine. Dr. J. A. Stephen, who is medical officer for the child welfare scheme in Aberdeen, will be in daily attendance. Lectures on health, the rearing of children, cooking, &c., will be given weekly, while the playground at the back of the building will be available daily for children under 5 years of age with their mothers. Mrs. Raitt, a member of the centre, has been successful in winning the competition for the Rhondda Mothercraft Challenge Shield, presented by Viscountess Rhondda and open to mothers attending welfare centres throughout Scotland. The subject of the competition was an essay on the important points in rearing children. The shield is held by the successful centre for one year, and if won three times in succession becomes the property of the centre.

The late Dr. J. Ironside of Laurencekirk.

The death took place at Laurencekirk on April 24th, in his seventy-sixth year, of Dr. James Ironside. Dr. Ironside was a native of Bonnykelly, in the parish of New Deer. He commenced practice in New Pitsligo, and in 1870 he took over the late Dr. Campbell's practice in Laurencekirk, where on his recent retirement he had just completed 50 years unbroken professional service. Dr. Ironside was an expert agriculturist and tenanted in succession several large farms. He was for a number of years a member of the town council of Laurencekirk and acted as chairman of the Lighting Society. He is survived by his widow and a family of three sons and three daughters.

Dr. Francis William Nicol Haultain has been appointed an additional inspector of anatomy for Scotland for a period of two months from April 20th.

May 3rd.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Dublin Corporation and an Eight-hour Day for Nurses.

THE corporation of Dublin has been in the habit of [illegible] grants, varying in amount, to the several Dublin ospitals. The corporation has now directed that as a ondition precedent to giving grants the hospitals must tablish an eight-hour day for nurses. This demand s one of the first results of the success of the Labour candidates at the recent municipal elections. It may be admitted that in Dublin, as elsewhere, nurses have been underpaid and sometimes over-worked, but an eight-hour day, however suitable a standard it may be for labour under ordinary conditions of continuous work, appears to be inapplicable in the case of discontinuous work such as nursing. It may not be possible for the hospitals to meet the demand of the corporation, and if the corporation presses its wishes the hospitals may find themselves deprived of support which, small as it is, can be ill spared at present.

Medical Man Killed in Motor Accident.

Dr. A. P. Spelman, of Dunmore, Co. Galway, was killed last week in a motor accident. When turning a corner the car skidded and overturned, pinning Dr. Spelman, his man, and a friend underneath. The other two were not seriously injured, but Dr. Spelman had been caught by the steering wheel and was killed instantaneously. He was only 26 years of age.

The Question of a Surgical Tuberculosis Hospital for Belfast.

Sir Henry Gauvain's report has now been received upon the suitability of "Graymount," the property on the north side of Belfast recently acquired by the corporation for a sanatorium for bone and gland tuberculosis. While making little of the climatic objections raised against the site, he objects in principle to the attempt to adapt a private residence to the purposes of a surgical hospital on the ground of expense and inconvenience. He advises the selection of a new marine site, laying down at length the desiderata to be borne in mind, "Graymount" to be used temporarily as a hospital and retained later as an after-care institution for certain types of surgical tuberculosis needing prolonged treatment. The report has been sharply criticised in the local press, which claims that the site, if unsuitable for one purpose is unsuitable also for the other, and which finds Sir Henry Gauvain's ideal scheme too Utopian. The familiar view is taken that it would be more economical for the present to concentrate upon the provision and improvement of housing, so as to resist tuberculosis generally, than to spend any money in a special direction.

Belfast Ophthalmic Hospital.

The main features brought forward at the annual meeting of the Belfast Ophthalmic Hospital—the oldest eye institution in Belfast—on April 27th were the great increase in patients—214 more eye patients and 190 more ear and throat, while the number admitted to the wards was almost double that of 1918; the good financial position—a debit balance of £5 4*s.* 9*d.* carried forward last year is now turned into a credit balance of £93 19*s.* 5*d.*; and the further progress of the proposed amalgamation of the Belfast Ophthalmic Hospital with the Ulster Eye, Ear, and Throat Institution. During the past year the combined staffs of the two hospitals have considered the matter and have wisely agreed on a good scheme of amalgamation, so as to have one great eye hospital worthy of the city of Belfast. The only difficulty is the legal one, how far the trust-deeds could be adapted to the proposal. It is really absurd that in these days of progress we should be tied by ancient forms, which are disadvantageous now both to the hospitals concerned as well as to the public.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Laënnec Institute.

A COMMITTEE was formed some months ago to work out the best way to commemorate the distinguished Breton doctor who invented auscultation 100 years ago, and thus gave to medicine not only a method fertile in results, but the stethoscope itself. The subscriptions have amounted to quite a considerable sum; the committee, having discarded the idea of an elaborate monument, has now decided on the much more useful establishment of a Laënnec Institute for the study o the prophylaxis and treatment of tuberculosis. The principal activities will be directed to the erection o laboratories, dispensaries, and sanatoriums, and the organisation of crusades in France and elsewhere The constitution of the Institute has recently bee adopted by a general meeting of the French Faculty o Medicine, which has at the same time nominated a administrative council. The officials elected includ Professor Letulle, president; Professors Gley, Calmette Vaquez, and Dr. Sergent, vice-presidents; Dr. Gallois general secretary; and M. Robert Laënnec, treasurer.

Lethargic Encephalitis.

The present epidemic appears to be on the decline few new cases are being reported. None the less, mor and more papers are being published on observation already made. M. Levaditi has published an interestin study of the filter-passing virus of this disease, whic can be inoculated into rabbits The lesions present microscopical characters which allow of a distinct differentiation of this virus from that of epidemic poliomyelitis, with which many clinical workers have sought to identify it M Netter has recently given a lecture at the Academy of Medicine on the infectivity of lethargic encephalitis He has now no doubt that it is infectious, though cases of direct infection are rare He quotes the case of a girl who came to Paris from a provincial family, a member of which developed the disease after her departure On arrival in Paris she apparently conveyed the infection to two cases which arose in her immediate neighbourhood. M Netter suggests that the virus is probably carried in the saliva He thinks that many people are naturally refractory and *may nevertheless be carriers of the germ* The isolation of patients would thus be desirable but impracticable, because the long duration of the disease and the frequency of relapses would necessitate a period of isolation disproportionate to the risk avoided

The Transmission of Syphilis in Animals.

M. Auguste Marie, principal medical officer of Villejuif Hospital, and M Levaditi, of the Pasteur Institute, have succeeded for the first time in the experimental transmission of syphilis in animals by sexual intercourse It will be remembered that these workers have differentiated a dermotropic virus,[1] the cause of cutaneous and mucous manifestations, and a neurotropic virus with which these experiments are concerned It is interesting to find that one animal can infect another by simple contact without any visible lesion Some light may be thrown on such controversial questions as conjugal general paralysis of the insane and the mechanism of hereditary nerve diseases by a development of these experiments, which have already shown that the infected male loses some of his sexual activity, while the infected female remains potentially fertile

Hospital for British Seamen on French Soil

The foundation stone of a hospital for sick or wounded British seamen was laid at Marseilles on May 2nd by Lady Burghclere, to whose efforts its erection is largely due The hospital will be well equipped, will contain 64 beds, and will afford treatment for all diseases It is situated in open country near the port, and when completed will doubtless be much appreciated by the mercantile marine The fund is not yet complete, £5000 being still needed.

May 4th

URBAN VITAL STATISTICS.

(Week ended May 1st, 1920)

English and Welsh Towns —In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had declined from 18 7 to 14 5 in the five preceding weeks, further fell to 14 2 per 1000 In London, with a population of nearly 4½ million persons, the annual death rate was 13 7, or 0 5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 5 4 in Oxford, 5 9 in Ilford, and 7 1 in Bath, to 24 1 in Sunderland, 24 3 in Tynemouth and 26 3 in West Hartlepool The principal epidemic diseases caused 321 deaths, which corresponded to an annual rate of 0 9 per 1000, and comprised 123 from measles, 80 from whooping cough, 55 from infantile diarrhœa, 44 from diphtheria, 12 from scarlet fever, and 7 from enteric fever Measles caused a death rate of 1 7 in Norwich, 2 4 in Newport (Mon), and 3 0 in Wigan, and whooping cough of 1 3 in Norwich, 1 4 in Bootle, 1 6 in Darlington, and 2 6 in Stockon on Tees The deaths from influenza, which had declined from 392 to 259 in the five preceding weeks, further fell to 202, and included 45 in London 11 each in Birmingham and Sheffield, 10 in Bolton, 9 in Bradford, and 8 in Halifax There were 1951 cases of diphtheria, 1831 of scarlet fever, and 12 of small pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 1965, 1845, and 23 respectively at the end of the previous week The causes of 27 of the 4846 deaths in the 96 towns were uncertified of which 4 were registered in London and 2 each in Birmingham, Liverpool, St Helens and Sunderland

Scotch Towns —In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had increased from 17 2 to 19 2 in the four preceding weeks, fell to 18 3 per 1000 The 438 deaths in Glasgow corresponded to an annual rate of 20 5 per 1000, and included 33 from influenza, 24 from measles, 4 from infantile diarrhœa, 3 each from small pox, whooping cough, and diphtheria, 2 from scarlet fever, and 1 from enteric fever The 100 deaths in Edinburgh were equal to a rate of 15 3 per 1000, and included 3 from measles, 2 from influenza, and 1 each from whooping cough and infantile diarrhœa

Irish Towns —The 215 deaths in Dublin corresponded to an annual rate of 27 0, or 1 5 per 1000 below that recorded in the previous week, and included 13 from whooping cough, 7 from measles, 4 from influenza, 3 from infantile diarrhœa, 2 from diphtheria, and 1 from scarlet fever The 158 deaths in Belfast were equal to a rate of 19 9 per 1000, and included 10 from influenza, 4 from whooping cough, 3 from infantile diarrhœa, 2 each from scarlet fever and diphtheria, and 1 from measles

Obituary.

SIR HENRY BURDETT, K C B , K C V O ,

EDITOR OF THE "HOSPITAL AUTHOR OF "HOSPITALS AND CHARITIES

ALL the medical profession will unite with us in regretting the not unexpected death of Sir Henry Burdett, which occurred on Thursday in last week as the result of a six months' illness, in his seventy-third year.

The son of a Leicestershire clergyman, Burdett began his strenuous life on a stool in a bank, but quickly manifested an interest in medicine, and was for a period a medical student both in Birmingham and in London But before completing his curriculum he found an outlet for his combined knowledge of business technique and hospital routine in the secretaryship of the Queen's Hospital, Birmingham To this post he was appointed at the early age of 21, and after holding it for six years was translated to the Seamen's Hospital, Greenwich, in a similar capacity. Here, also, he remained for six years, and so impressed the authorities with his industry, capacity, and power of organisation that he was appointed to the important post of secretary to the Share and Loan Department of the Stock Exchange In this position he remained for 17 years, and the work that he did there has left a permanent impression on the commercial life of the country, for he compiled "Burdett's Official Intelligence," a repository of information on Stock Exchange securities, and wrote many papers on Imperial, colonial, and municipal finance, and others illustrative of the influence of modern invention upon industrial developments It was during this time that his book entitled "Prince, Princess, and People ' appeared and attracted influential attention Written as a Christmas Number of the *Hospital*, it grew into a sketch of social progress and development, as illustrated by the public life and work of the late King and of Queen Alexandra, when Prince and Princess of Wales

If he had done no more than this he would be displayed as a valuable servant of the public, but Burdett is better known, not only to medical men but to the world, for his work in behalf of voluntary hospitals and the calling of nursing As hospital secretary he had at his fingers ends the real needs of these institutions and the best methods of securing voluntary assistance Over 30 years ago he saw that there was a middle class population, between those whose environment allowed of complete treatment in their homes and those who had a right to complete charitable assistance, for whom no institutional treatment was provided, and the result was the opening of the first hospital for paying patients in Fitzroy square Later he organised the first hospital conference, which led in 1884 to the institution of the Association of Hospital Managers In these efforts, which were revolutionary in many directions in their day, he secured, now and again with some difficulty, the coöperation of the *British Medical Journal* and THE LANCET, but later he founded his paper, the *Hospital*, more exactly to express the side of medical service with which he was personally acquainted, and to record the activities of hospital and nursing life. He had already been one of the earliest workers in the cause of the Hospital Sunday Fund, which was founded at the Mansion House in 1873 during the mayoralty of Sir Sydney Waterlow. The pattern for this great movement was supplied by the "Hospital Sunday" previously inaugurated by Canon Miller in Birmingham, and the translation of the idea to London, with its subsequent huge success, will always be associated with the names of Waterlow, Burdett, and the then editor of THE LANCET, James Wakley.

---

[1] THE LANCET, April 10th i 829

In 1887 Burdett established the Royal National Pension Fund for Nurses, and although in his many efforts to organise a system of training for nurses his views were often challenged, what he did for the profession of nursing was immensely valuable, as everyone will admit who knows the history of the Pension Fund. And in yet another way he has placed the philanthropic world, as well as the medical profession, under a deep obligation, for in 1883 he brought out "Hospital Charities: a Year-book of Philanthropy," which has become the leading book of reference on all that concerns the organisation of hospitals and the life and work of their nursing staffs. It was right that such a man should receive public honour, and when Sir Henry Burdett was created K.C.B. in 1897, and K.C.V.O. some ten years later, no one who knew the devoted nature of his services thought that such rewards were over-generous.

Personally, Burdett was an interesting and attractive man. A former colleague writes of him:—

> Those who at any time worked in close association with Sir Henry Burdett and visited him at The Lodge, Porchester-square, knew him as a kindly, hospitable, home-loving man. Until quite recent years, when death took one after another from the home circle, he was singularly happy in his family life. One always found him in the large library on the ground floor overlooking the lawn, where he spent a large part of the day and did most of his work. Even in personal conversation he never could subdue the instinct for oratorical effect, for the dramatic pause with glittering eye and wide-armed gesture. His books and articles were dictated to an invisible audience, and, as a result, his literary work often had something of the diffuseness and floridity of platform speech, with the characteristic personal touch a little caricatured by cold print. Nevertheless, he was an accomplished and alert journalist, eager for the success of his papers, and well versed in the various branches of editing and publishing. His mind in general moved along large lines towards large objectives; but while he much preferred to depute the working out of details to others, he could, if need be, get down to the smallest parts of a big scheme, and handle them with bold dexterity. He was a man of strong and commanding personality; by no means an "intellectual," but with very great mental powers. The qualities that especially stand out in one's memory of Sir Henry Burdett are his unquenchable enthusiasm, the bigness of his ideas and projects, and his persuasive eloquence. As a colleague he was most kind, courteous, loyal, and considerate; he could not be shaken from his opinions, but when he said he would do a thing he kept his word.

To this intimate tribute we subscribe from our own knowledge. Burdett's courage, sincerity, and industry were remarkable, and the fruits of his qualities will be reaped by many to come.

He married in 1897 Helen, daughter of Mr. Gay Shute, who bore him two sons and two daughters, and predeceased him by a few months.

SIR KENDAL FRANKS, M.D., F.R.C.S.IREL.

Kendal Matthew St. John Franks, whose death in Johannesburg on May 1st is announced, was in his seventieth year. A native of Kilkenny, he took an Arts degree at Dublin in 1872, graduated in medicine three years later, and spent some time at Leipzig. Elected early to the staff of the Adelaide Hospital, Dublin, he became its senior surgeon, Vice-President of the Royal College of Surgeons in Ireland, and examiner in surgery at the University. The Boer War took him to South Africa as consulting surgeon to the forces from 1899–1902. He was rewarded with a C.B. and then settled in Johannesburg, where he became honorary surgeon to the hospital and president of the South African Committee of the British Medical Association. He received a knighthood in 1904.

"Audi alteram partem."

X RAY DATA IN DIAGNOSIS OF CARDIAC ENLARGEMENT.

To the Editor of THE LANCET.

SIR,—It appears that certain methods of detecting and estimating cardiac enlargement by means of the X rays (I find from letters I have received) are by no means generally known, although two of them, (B) and (C), in the *Archives of Radiology and Electrotherapy*, of May, 1919, are referred to as having appeared in THE LANCET of Nov. 30th, 1918 (p. 750). These methods, as carried out by me, three in number, are as follows:—

(A) *The "Cardio-Thoracic Ratio."*[1]—With the focus of the X ray tube at a distance of 6 feet (but 2 feet is just as good), the greatest transverse heart diameter (calculated by adding the part-diameter of heart in right fourth intercostal space to right of median line to the part-diameter in left fifth space to left of median line), should normally be 39–50 per cent. of greatest diameter of thorax, in mid-inspiration. Over 53 per cent. in adults is pathological.

(B) *The "Index of Depth."*—With tube-focus at a distance of 2 feet, an exposure is made—of a half second is best—the tube is moved 10 cm. to right and a similar exposure is made on same X ray plate (or better, a Dupli-Tized film with two intensifying screens). Two impressions of diastole of heart are seen after development. In the adult an apex-displacement of 7–14 mm. is normal (20 mm. and above is pathological).

(C) *The "Angle of Disappearance of the Apical Shadow."*—With the fluorescent screen on the dorsum, rotate patient's body in the upright screening-stand until cardiac apex coincides with spinal apophysis; measure the angle made between the bi-scapular line and the screen-surface. If of 25–30° it is normal, over 30° indicates augmentation of the ventricular volume.

As regards (B), the ideal exposure is for the time of one cardiac cycle, not more and not less, as far as possible. What is wanted is two well-defined impressions of two separate diastoles.

(C) A simple goniometer is made from two 10 by 6 plates covered with thick paper and hinged; the exact angle is easily measured with it.

The ortho-diagraphic and telephotic methods are of course well known.

I am, Sir, yours faithfully,
C. FRED. BAILEY.

Royal Sussex County Hospital, Brighton,
May 1st, 1920.

BLIND MASSEURS.

To the Editor of THE LANCET.

SIR,—In your issue of April 17th, there appeared a letter from Miss Magill on the subject of blind masseurs. With reference to the early paragraphs of her letter I need only say that the writer gives expression to opinions which are not shared by all authorities, as has been clearly shown by the recent correspondence in your journal. With regard to Miss Magill's statement that the sighted workers in a large department invariably find that they have extra labour thrown upon them where a number of workers are blind, this I can assure your readers is by no means the experience of officials in establishments where blinded soldier masseurs are employed.

Miss Magill next dwells upon the depressing effects upon the patients of the ministrations of blind masseurs. In regard to this, and to the efficiency of blind masseurs generally, I cannot, I think, do better than quote from a letter which I have received from Major-General Sir Robert Jones, C.B., F.R.C.S., L.R.C.P., which states:—

> "The work that your blind masseurs do is very exceptional in quality. They are in every sense of the term a great success. I find them all intelligent and possessed of a wonderful gift of touch, together with keen enthusiasm for their work. Apart from their qualities as masseurs, I think they have an extraordinarily good psychological effect upon their patients. I consider institutions which secure the services of these men trained at St. Dunstan's very fortunate."

Archiv. Rad. and Elect., February, 1920, p. 301.

Miss Magill ends her letter by saying that blind masseurs are apt to feel their work to be more than they can accomplish. In regard to this, I can only say that I am in very constant communication with the great majority of the blinded soldiers who have been trained as masseurs at St. Dunstan's, and that I have never heard anything of this kind from any of them. It may be that Miss Magill refers to the two cases of men who, when they got into actual work, found that their health was not sufficiently good to endure the strain which the active practice of massage involves But 2 out of 92 is not a very large percentage, is it?

I am, Sir, yours faithfully,

ARTHUR PEARSON.

The Association of Certificated Blind Masseurs,
Great Portland street, W , April 26th, 1920

To the Editor of THE LANCET.

SIR,—In THE LANCET of April 17th there is a letter from Miss E M Magill on the above subject. The letter abounds in sweeping generalisations, but I sought in vain for a statement verified by fact. For instance, the following paragraph appears —

> "I should like to point out that the sighted workers in a large department *invariably* find that they have extra labour thrown upon them where a number of the workers are blind, as it is *universally admitted* that special cases have to be picked out for the latter " (The italics are mine)

Now as I have had charge of the physical treatment departments at Alder Hey for nearly four years, when many thousands of cases have been treated by massage, at times as many as 600 treatments being given daily in the massage department, I may claim to speak for a "large department." Further, we had six blinded masseurs from St. Dunstan's on the staff of this department. I most emphatically deny that any of the workers had extra work thrown on them because of the presence of blinded masseurs. Indeed, the reverse was the case, as cases requiring especially vigorous treatment were spared the masseuses, and given to the masseurs I might also add that certain cases *must* be treated by a masseur, as it is obviously inexpedient for them to be manipulated by a masseuse. Further, I deny strongly that "special cases have to be picked out for the blind masseurs " As a matter of fact, if there has been any "special selection " it has occurred when a particular case required especially careful and skilful massage. Such a case was invariably allotted to the head blinded masseur, whom I considered by far the best exponent of the art amongst the staff. So that in fact the *masseur* was "picked out" for the case

A very important point in the treatment of soldiers and pensioners by blinded masseurs is the psychic element There is comfort, sympathy, and that "fellow feeling which makes one wondrous kind" in the knowledge that one wounded pensioner is being treated by the whole hearted efforts and enthusiastic endeavours of a fellow-disabled pensioner, and who can deny that this mental concomitant to the massage has not an efficacious influence on the treatment? Very frequently have I had a request from a patient to be allocated to a blinded masseur. Still, Miss Magill states in her letter that "many medical men tell her that frequently patients object to being treated by blind masseurs " Such has not been my experience I must candidly admit that when it was first suggested that a blinded masseur should be included in the staff at Alder Hey I was sceptical as to the practicability of such an experiment; but when I found what capable, careful, enthusiastic and skilled workers were turned out by St. Dunstan's, I was ashamed of my scepticism, and thereafter it was my constant endeavour to obtain more blinded masseurs. I was extremely fortunate in obtaining six of them, and a more loyal, industrious, and capable sextet it would be impossible to find. Frequently Sir Robert Jones, as well as other surgeons on the staff at Alder Hey, expressed eulogistic opinions with regard to the results of the treatment by the blinded masseurs

From the above remarks it will be understood that I feel it incumbent on me to resent unkind and unfair attacks which are calculated to traduce their ability, and to militate against their chances of obtaining an honest livelihood in a calling for which they are capably trained, and in which their tragic disability proves to be no hindrance

Finally, may I adduce one further proof of my contentions? Several months ago—I am proud to say at my instigation—a clinic was opened at Liverpool for massage, remedial exercise—and electrical treatment, and staffed by four blinded soldier masseurs. I am glad to state that they have had a remarkable number of patients, both private and pension cases, and have had signal success That there has been success I am prepared to vouch for by the testimony of patients themselves, as well as the medical men who have sent them. As a last word may I have Miss Magill's permission thus to paraphrase the old adage, "De militibus cæcatis nihil nisi bonum"?

I am, Sir, yours faithfully,

W. H. BROAD, M D.,
Major, R A M C (T F)

Rodney street, Liverpool, April 24th, 1920

To the Editor of THE LANCET.

SIR,—In fairness to other candidates, may I be allowed to comment on Sir Arthur Pearson's letter in your issue of April 24th? It is there remarked that "in the recent *examinations* of the Incorporated Society of Trained Masseuses" a blinded soldier from St Dunstan's "passed first *in all subjects*," a statement which would seem to imply that the same candidate passed first in all three examinations. The man in question did excellently in the examination in massage, and headed the list of successful candidates, the marks in the separate subjects of anatomy, theory and practice of massage not being published. In the special examination in exercises as an adjunct to massage, held for blind candidates only, a fellow student from St Dunstan's gained the first place, whilst, as is no doubt well known to many of your readers, our examination in medical electricity is not open to the blind —I am, Sir, yours faithfully,

E W. BLISS,
Chairman of Council, Incorporated Society of Trained Masseuses

157, Great Portland street, W ,
April 28th, 1920

*** The question has been sufficiently discussed It is clear that the blinded soldier makes an admirable masseur, that there must be circumstances in which he is at a disadvantage; and that all engaged in the organisation and employment of massage share in deep sympathy for the honourably wounded and in determination to give them full opportunity for their large range of valuable service.—ED. L

BRADFORD'S MUNICIPAL HOSPITAL SCHEME

To the Editor of THE LANCET.

SIR,—In your leading article on Hospital Principles you allude to the establishment of a municipal hospital in this city. May I inform you that the chairman of Bradford Corporation Health Committee, at an interview granted by request to some members of the staffs of our voluntary hospitals, gave us to understand that he himself has no intention or wish to do more than supplement the work of the voluntary hospitals by the municipalisation of St. Luke's? At present that step will add only some additional 150 or 200 beds to those already required for other purposes (maternity, venereal, children's, infants', and so forth), a number, of course, totally inadequate for Bradford's needs He therefore does not see that the voluntary hospitals will be much or soon affected by the scheme The chairman's view and desire is one thing; the march of events is quite another. When one set of hospitals can draw on the rates compulsorily for their support, while others depend on freewill offerings, there can be little doubt that in a short time the rate supported hospitals will choke the others.

In my judgment we ought to have settled questions of principle before considering details; and the question of principle is: Has a sick person, whatever his means, a right to demand free attention at the cost of his town or country and when did he obtain such right: If he does so, is he not a pauper, even if he is not called so? If so, ought he to have the right of voting his own subsidy and of determining the scale on which it is to be provided? Is not the granting of such a right a danger to the town and to the State?

I am, Sir, yours faithfully,

Bradford, May 1st, 1920. A. RABAGLIATI.

INFANTILE DIARRHŒA AND VOMITING.

To the Editor of THE LANCET.

SIR,—As Dr. G. Douglas Sherwood says, in his paper in THE LANCET of April 24th, now is the time when "the preservation of infant life becomes of the utmost importance," and with your permission I respectfully suggest a cause other than infectivity. The disease primarily affects children at an age when the skin is unpigmented and has no power of producing pigment. Its seasonal incidence corresponds to the greatest amount of sunlight—that is to say, a comparative absence of sunlight corresponds to absence of this disorder. The diarrhœa and vomiting of very young children is more common in the bottle-fed than in the breast-fed, and may be accounted for by the breast-fed receiving more maternal care than the bottle-fed.

The similarity between the method of attack of this disease and sunstroke points to their being due to the same cause. Children are frequently attacked by the disease after many hours' removal from the sunlight, just as most of the cases of sunstroke among our soldiers in India occur in the night. Therefore I suggest that the electrical effect of light penetrating the skin may cause a dissociation of the metal calcium in the blood. It is well known, and has been known for many years, that the regular administration of lime-water to infants during the summer months is a valuable prophylactic.

I am, Sir, yours faithfully,

Didsbury, Manchester, May 1st, 1920. R. CRAWSHAW HOLT.

THE RELATION OF GENERAL MEDICINE TO OPHTHALMOLOGY.

To the Editor of THE LANCET.

SIR,—In the interesting and revealing letter printed in your issue of May 1st Mr. Charles Higgens relates a number of instances in which ophthalmic surgeons have been able to recognise that some of the local conditions which come under their observation are associated with, and in particular instances dependent on, more or less remote disturbances or generalised pathological states. In accordance with a healthy professional tradition these observations, and the lessons to be drawn from them, have been placed at the disposal of the medical profession, with obvious advantages both to practitioners and to patients. Mr. Higgens may well claim gratitude both for himself and his colleagues, and personally I was under the impression that so generally was this claim allowed that there could be no need to repeat it. As it appears Mr. Higgens considers repetition necessary, I shall not dispute his better judgment. Whether, however, the beginning of knowledge in this direction was really so recent as 1888 (the date Mr. Higgens selects) may be doubted, and a similar remark applies to the suggestion that the debt is due entirely to the ophthalmic surgeons. To take but a single example. I have before me a book of some 400 pages entitled, "The Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys; also in Certain other General Disorders," and this was published, not in 1888, but in 1871; and its author is the physician who, amongst other distinctions, now occupies the Regius Chair of Physic in the University of Cambridge. In these circumstances I for my own part cannot confine my gratitude to the narrow circle which Mr. Higgens defines. There were brave men before Agamemnon, and, to adapt the phrase to the present issue, not all of those worthy of fame-boasted the art and craft of ophthalmic surgery. If Mr. Higgens will consult the book whose title I have quoted he may perhaps (though the ophthalmic surgeon has "no use" for the physician) be led to doubt whether the unqualified statement that "albuminuric retinitis is a late symptom and its occurrence is a sign that the patient is approaching his end" is quite such an accurate contribution to medicine as its dogmatic form proposes.

To pass from historical performances to the present position, Mr. Higgens, from the fashion in which he uses the terms "ophthalmologist" and "ophthalmic surgeon," would appear to regard ophthalmology and ophthalmic surgery as equal and synonymous terms. How such a proceeding can be justified I am at a loss to imagine, and it may find a practical criticism in the fact that to a recently founded lecturership in ophthalmology there was appointed but the other day a professor of anatomy, and that the predecessor of this gentleman was a physician. Everyone is ready, and more than ready, to recognise the values and triumphs of the ophthalmic surgeon, but to present him as the possessor of an exclusive interest and capacity over the whole field of ophthalmology is to approach perilously near the region of the ridiculous.

I am, Sir, yours faithfully,

Harley-street, W., May 3rd, 1920. C. O. HAWTHORNE.

LICE AS A CAUSE OF RINGWORM.

To the Editor of THE LANCET.

SIR,—I was very much interested in Dr. A. E. L. Wear's letter in THE LANCET of May 1st suggesting a causal relationship between lice and ringworm. It is certainly very probable that head-lice can and do act as carriers of the spores of the *Microsporon audinii*, but before accepting this as the only, or even main, mode of infection I would submit with due deference that the logic of the argument seems somewhat strained. With two such common conditions the class most likely to be infected with either or both is the same—namely, those people whose heads receive least attention from soap and water, or brush and comb; and these are the sufferers—the children in the elementary schools.

Again, anyone who sees large numbers of children suffering from lice or ringworm of the head must have been struck by two facts—namely, that the site of predilection for ringworm is a wide band running along the vertex of the scalp, whereas the site of predilection for pediculi capitis is the occiput. I agree with Dr. Wear that the question of the infectivity and incidence of ringworm of the head is one of some importance, but I am inclined to think that it is not quite the simple problem his letter suggests. For instance, in my experience ringworm is much commoner in blondes than in brunettes (allowing for the preponderance of the blonde type in England), and in those with straight hair than in those with wavy or curly hair. Also ringworm dies out at puberty or thereabouts; the spores seem unable to find their natural pabulum on adult heads, but pediculi do not by any means forsake the heads of adolescence or even maturity.

I am, Sir, yours faithfully,

Sheffield, May 3rd, 1920. E. F. SKINNER.

DEATH OF DR. H. M. ALLEN.—Dr. Henry Marcus Allen, who died at Avonmore-road, Kensington, on April 23rd, after an illness of over two years' duration, was formerly a well-known practitioner in Brighton. He was a son of Mr. Thomas Marcus Allen, and of a Somersetshire family. Born in 1844 at Brighton, Henry Marcus Allen spent his boyhood there, and at 14 became one of the original members of the 1st Sussex Rifle Volunteers, sworn in at the Town Hall in 1858. After spending some time at Oxford and Paris he entered St. Bartholomew's Hospital, where he qualified L.S.A. and M.R.C.S. in 1871 and held the posts of house physician, resident physician-accoucheur, and obstetric assistant. Two years later he was admitted a Member of the Royal College of Physicians of Edinburgh, and was elected a Fellow in 1882. In Regency-square, Brighton, where he started to practise, he won a large connexion, besides holding a number of appointments. Subsequently he moved to Hove, and latterly practised at East Sheen. Although it is many years since he lived in Brighton and Hove, Dr. Allen had not been forgotten, and his death was regretted by a large circle of friends and former patients. The funeral took place at the Parochial Cemetery, Brighton

The Services.

ROYAL NAVAL MEDICAL SERVICE

Surg Lieut G A M Anderson is promoted to Surgeon Lieutenant Commander

ARMY MEDICAL SERVICE

Col W E Hardy retires on retired pay

Temp Col Sir A Chance relinquishes his commission and retains the rank of Colonel

ROYAL ARMY MEDICAL CORPS

Lieut Col B Forde is placed on retired pay

The undermentioned Lieutenant Colonels retire on retired pay S J C P Perry, W L Baker, J G Churton, T Biggam, H A Davidson

Major N D Walker to be temporary Lieutenant Colonel whilst specially employed

The undermentioned relinquish the acting rank of Lieutenant Colonel Majors T J Potter and P C T Davy, Capt C H K Smith

Major M P Leahy is placed on retired pay on account of ill health caused by wounds

The undermentioned relinquish the acting rank of Major Capt A E Richmond, Temp Capts C D Faulkner, B Knowles O R L Wilson, J R Griffith, D Fisher

Capt W T Hare resigns his commission and is granted the rank of Major

A L Aymer, late Captain R A M C, to be Captain

Lieutenants (temporary Captains) to be Captains G H Barry, M McG Russell, F G L Dawson

To be temporary Captains G Cock late temporary Captain, E S Joske, late Captain A A M Corps, H Bell, late Can A M C

Officers relinquishing their commission —Temp Majors retaining the rank of Major W S Haughton H E L Canney Temp Capt J E Ainsley, on transfer to the Indian Medical Service Temp Captains granted the rank of Major H N Webber S E Picken N E Kendall, C C de B Daly, R Massie, J H Peek Temp Captains retaining the rank of Captain J S K Smith S W H Stuart, A E Sanderson, V D Pennefather F Shearar, G B Buckley, A P Mitchell, A H Holmes J F O Mahoney, R G Higgen, G H Winch, R L Hughes C R Macleod, C C Brewis, A Hines S Broderick, H Hannigan, D F Brown, L W Evans R C Poyser, R B Johnson, T J Cobbe, B C Haller, E D S Heyliger, P Black, W Forsyth, W N H Bell, D J Bedford, J S Williamson J Lascelles, T D Miller, J L Meynell, H W Hues R Hodson E G B Carpenter, E R Holborow J J Robertson W S I Robertson, M Dockrell C L Spackman J H Marshall W G Hopkins, T R Fulton, S W Milner, A C Meek J M Anderson, D O Richards H S Stockton, T G Elsworth, H G Parker, T B Vaile, W J F Symons N B Laughton, C C Okell

Medical Branch —Lieut Col G N Biggs (Major, R A M C T F) relinquishes his temporary R A F commission on return to Army duty and is permitted to retain the rank of Lieutenant Colonel

Capt C E Thwaites is transferred to the unemployed list

Parliamentary Intelligence.

HOUSE OF LORDS

WEDNESDAY, APRIL 28TH

EXPERT INQUIRY ON SHELL SHOCK

Lord SOUTHBOROUGH called attention to the different types of hysteria and traumatic neurosis, commonly called "shell shock," from which many soldiers suffered during the war, and referred to the death penalty inflicted upon men by courts martial on the charge of "cowardice" (without inviting any reopening of the evidence in such painful cases), and moved that the Government should make inquiry either by a Select Committee of the House of Lords or by a Departmental Committee into the expert knowledge derived by the army medical authorities and the medical profession with the object of recording for use in time to come the experiences of the war, and to advise whether by military education or otherwise some scientific method of dealing with such cases could not be devised He said this was a vast and complicated subject which must be approached with care and circumspection The subject of shell shock could not be referred to with any pleasure All would desire to forget it—to forget the cases extraordinary and mysterious, with which we had been confronted, to forget the roll of insanity suicide, and death, to bury our recollections of the horrible disorder, and to keep on the surface nothing, but cherish the memory of those who were the victims of the malignity But they could not do this, because a great number of the cases of those who suffered from shell shock and its allied disorders were still upon our hands and deserved our sympathy and care

The Identification of Shell Shock.

It was also our duty carefully to record all the knowledge and experience acquired by our medical and administrative authorities He was inclined to think that the disorder now called shell shock ' must have occurred in some of the fierce and bloody battles of the past and that among its victims were many whose condition was never properly understood and who suffered the penalty of death He believed that he was right in saying that whatever might have been the diagnosis at the beginning of the war there was now a fairly general consensus of opinion here, in France, and in America, that they were cases of varying and differing types of hysteria or traumatic neurosis common and well known in civil life well understood by medical practitioners and frequently met with in railway and other violent accidents If it was a fact that a true identification of the disorder was wanting in the early months of the war he feared that through inadvertence and want of knowledge dreadful things might have happened to unfortunate men who had in fact become irresponsible for their actions

Shell Shock and Hysteria

It was clearly not long however, before our army medical authorities in common with the French, fully realised the gravity of the disorder and appreciated that if one understood hysteria they were well on the way to understand "shell shock ' This was all for the good but it did not in fact lighten responsibility, for hysteria was a very serious and dangerous malady, and not only did it present itself in various forms and types, but it became in a sense contagious because men became open to suggestion through expectation And only too often such expectations were realised If it might be assumed that 'shell shock was now recognised to be a type of hysteria differing but little from the traumatic psycho neurosis observed in civil life then it should be amenable to the same therapeutic measures both for prevention and cure These and other matters relating to treatment offered an interesting field for inquiry evidence, and records There was evidence that ' shell shock " or hysteria was not confined to the untrained soldier This meant, no doubt that in some cases after wear and tear the nervous system refused to do more But it also meant that the seasoned soldier had probably suffered already from shell shock had been invalided, and then returned to the front Was it not worth while to inquire whether when a man had been badly damaged by 'shell shock," it was safe either for himself or his colleagues to allow him to return to the fighting line? There were many thousands of cases of shell shocked men discharged to pension or invalided out of the service Some investigation, not of individual cases but of classes of cases might be expedient In quasi mental cases he could imagine no more miserable fate for a patient than a continued course of absolute idleness and the health and condition of a large number of men doing nothing but draw their pension might be greatly improved by an organisation designed to give them a little work as a beginning He feared there were a number of cases of mental type so severe that the hope of the restoration of the mind had practically been abandoned. Were these to be permanently kept in homes, and was the treatment there the most desirable for them? Again, was it wise that various classes of the disorder should be mingled together? The real question in cases of dereliction of duty was whether there was loss of will-power. What power had the courts-martial to make inquiry into the condition of the man's mind? It was obvious that in cases of hysteria to ascertain truly the condition of the prisoner's mentality and will-power was of the first importance. He gathered that where a plea of insanity was entered at a court-martial the medical officers were not allowed to report generally on the prisoner's state of mind. The man, possibly one with a low order of mentality, might have entirely lost his wits on the day of the battle, and a few weeks later might have practically recovered. In recent years, through the humanity of the judges and the establishment of the Court of Appeal, the rules in McNaughton's case —the case of the murderer of Drummond, Sir Robert Peel's secretary—had been relaxed and the judges had approached the position that responsibility might be abrogated by loss of control if arising from mental disease or infirmity and not through the accused person's own conduct. But it would appear to be otherwise under military law, under which, if the defence of insanity was raised, it could only be resolved by a rigid application of the McNaughton rules.

Military and Civil Considerations.

Inquiry might fairly be made as to whether the military and the civil law should not be put upon the same footing. Was it possible, the noble lord asked, to prepare the minds of soldiers against the disasters of hysteria and neurosis? Dr. Morton Prince, a distinguished physician of Boston (Massachussetts), had given great attention to the subject at home, at the base, and in the hospitals of France and England. He was of opinion that it might be driven into a soldier's mind as part of his ordinary training that "shell shock" was a form of hysteria, due to his own thoughts and fears, and external suggestion arising from the condition of the modern battlefield, and that as long as he received no physical injury there was little danger to be apprehended from the disasetr. The efficiency of the army and of future armies might well be impaired by shell fear (as they called it in America), and it was worth considering whether some method of giving confidence by training and education might not be devised by a committee. Upon the committee of inquiry it would be important to have the best army medical representation that could be found, and he suggested that their lordships' House might be represented by Lord Dawson of Penn, until recently Sir Bertrand Dawson. Two representatives of the House of Commons would also be important. A naval medical officer might be put on the committee, as the results of shell fighting at sea were distinctly different from those of shell fighting on shore.

Lord Horne's Views.

Lord HORNE, as a general officer who had commanded large forces in the field, cordially supported Lord Southborough's motion. He was convinced from his own personal experience that there was a tremendous field of research open to any committee established with the object referred to by the noble lord. In the later part of the war if there was the shadow of a suspicion that a man's crime might have been caused by any of the forms of hysteria which were included under the term "shell shock" he could confidently state that the sentence was not confirmed until the accused had [illegible] under the observation of medical authorities or detained for a time at one of the detention establishments and given every opportunity of allowing those in authority to arrive at a decision, whether his mental balance had in any way been affected or not. He was much struck by the suggestion that an inquiry by a competent committee might lead to some form of mental exercise that would enable them to train soldiers to endure the nerve-shattering conditions which led to this form of "shell shock." Personally, he thought it was extremely probable that some methods might be devised which would lead to that end. But the term "shell shock" should not occupy people's minds too much, because many of those whose mental balance gave way during the war did not lose their self-control from anything to do with a shell, but from the general effects of extreme tension on a highly organised nervous system. It was those, possibly, of the lower mentality and lower organisation; those whom nature had endowed with a more easy-going temperament, who were less likely to suffer from any form of "shell shock." Fear, after all, was met by whatever effort was necessary to control the nerves. Under the novel conditions of a modern battlefield there was no man who did not suffer from fright. The man who got through was the man who retained the power of controlling his nerves.

The Need for Special Medical Advice.

Viscount HALDANE said he agreed with the grounds stated by Lord Southborough, but he was not quite sure that the remedy he proposed by his motion was right. It was now known that want of mental control was in a good many cases the result of an actual physical cause. For instance, the shock of an explosion might physically inhibit the action of the nerves which controlled breathing; the supply of oxygen to the blood, and therefore to the brain, might be impaired. The result was that the individual was for the time being, and perhaps for some time after, a different personality. There was much more than a question for the ordinary experts. All that could be done, he thought, was to collect the very valuable body of evidence which had been got together lately. There were investigations at the Taplow Hospital, under the direction of the War Office, which were of the utmost value, and others had been going on all over the country. He agreed that the matter required the closest investigation. It had too often, however, been the custom because a man was a very eminent medical man to ask him to investigate a branch of a very great science which had ramifications with which he was not familiar. In a matter of this kind they ought to get together a small body of picked men of the highest eminence in this particular branch of investigation. A small investigating committee of this kind brought together by the War Office, could, roughly, at all events, lay down certain standards.

Expert Inquiry Granted.

Viscount PEEL (Under Secretary for War), replying for the Government, said that the instructions to courts-martial during the war were that where the soldier in his defence or in mitigation of punishment urged a substantial plea on medical grounds a medical witness was invariably to be called either to substantiate or rebut the case before the finding, if it was in defence, and afterwards, if it was urged in mitigation of punishment. In practice the court adjourned and a medical board was held; and on the adjourned hearing one or more members of the board would be called to give evidence as to the facts observed and their conclusions on these facts. A mental specialist was always included if their was any suggestion of "shell shock" or any other kind of mental or nervous derangement. A medical board was always held before any action was taken to confirm a death sentence. The number of cases in which such sentences were carried out was exceedingly small. For cowardice 18 death sentences were carried out and 266 for desertion. The total number of death sentences carried out was 343, whereas the total number of such sentences passed on officers and men was 3076. As regards the request for an inquiry, the view of the Government was that great advantages might be obtained from such an investigation. Many of the nervous and mental conditions encountered were entirely new to many of the medical officers concerned, and there had been a great many expressions in different medical journals of their individual views on the subject. It was thought that it would be of great value if these different views could be gathered together and thoroughly investigated by such a committee as had been suggested. The composition of the committee was a matter for consideration later. Besides experts in the particular subject, it might be considered whether from the discipline side a lawyer and a soldier might also be included.—The motion was agreed to.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 28TH.

Indian Medical Service Pensions.

Colonel YATE asked the Secretary for India if he could now state what increase was to be made in the pensions of the widows, children, and dependents of deceased officers of the Indian Army, the Indian Medical Service, and the Royal Indian Marine.—Mr. MONTAGU replied: I am still awaiting the views of the Government of India. I have again impressed on them that the matter is urgent.

Contaminated and Infectious Stores.

Mr. JOHN DAVISON asked the Minister of Health whether he had received any resolutions of protest from the various trade-unions and other organisations in the district of Bow and Bromley strongly protesting against the dumping of infectious and contaminated surplus stores of Government war materials in that district, and demanding that all such stores deposited there should be destroyed at once and no further quantities allowed to be landed in this country as, in their opinion, this dumping was responsible for the outbreak of small-pox in that district; and whether he could state what action he proposed to take in the matter.—Dr. ADDISON replied: I have received a resolution of protest from the Bow and Bromley Local Labour Party in regard to this matter. The stores referred to are in course of removal, and it is expected that the removal will be completed by the end of next week. These stores will be thoroughly disinfected and deposited in premises which have been secured for this purpose outside London. The disinfection is being carried out under the supervision of one of the medical officers of the Ministry of Health. I am informed that no stores belonging to the Ministry of Shipping which are known to be infected are allowed to be placed in store until they have been adequately disinfected.

The Supply of Midwives

Mr **BRIANT** asked the Minister of Health if he would state the number of practising certified midwives in the United Kingdom and the approximate number required for the proper care of maternity cases, and what steps, if any, the Ministry proposed to take in order to secure that an adequate supply of midwives should be available.—Dr **ADDISON** replied in a written answer According to the last report of the Central Midwives Board the number of women entitled to practise as midwives on March 31st, 1919, was 44,166, but the number who gave notice of their intention to practise in 1918 was only 11,298 No useful estimate can be made of the total number of midwives required The shortage which exists in some districts is due to the fact that the number of cases within reach is too small to enable a midwife practising independently to make a living The Ministry have continued the policy of the Local Government Board of urging local authorities and nursing associations to subsidise midwifery in the more scattered districts and of paying grants in respect of such subsidies By this means the proportion of the rural population served by trained midwives has increased since 1917 from 51 per cent to 65 per cent, and steady progress is being made Nearly all the county councils and county nursing associations have framed schemes for extending the midwifery service of their counties A number of local authorities in urban areas have also, with the assistance of the Ministry, subsidised the provision of trained midwives in parts of their districts in need of this service A grant in aid of the training of women as midwives has been authorised, and is being administered by the President of the Board of Education

After Care of Consumptives

Major **ENTWISTLE** asked the Minister of Health whether his attention had been drawn to the report issued by the Kingston upon Hull Insurance Committee dealing with the administration of sanatorium benefit for the year ending Dec 31st, 1919, in which it was pointed out that a large proportion of the number of persons who applied for sanatorium benefit died within a comparatively short period after treatment where such treatment was not followed up by effective after care, whether he was aware of the striking improvement which had taken place in Hull since the establishment of an after care committee, and, if so, whether it was the policy of the Minister in his scheme for combating tuberculosis that after care would form an integral part thereof and receive liberal financial encouragement from Imperial sources.—Dr **ADDISON** replied The answer to the first three parts of the question is in the affirmative As regards the last part, the financial arrangements in connexion with the scheme for combating tuberculosis are under consideration

Diet and Clothing for Tuberculous Ex soldiers

Mr **RUPERT GWYNNE** asked the Pensions Minister whether his attention had been drawn to the fact that it was not generally known among ex Service men suffering from tuberculosis that they were entitled to extra diet allowance, and special bedding and clothing where necessary, and if he would give instructions to local War Pensions Committees to have this information more widely circulated —Major **TRYON** replied Inquiries which have been made do not support the suggestion contained in the question Moreover, the conditions under which special diet and clothing can be provided are fully set out in the Local War Pensions Committee Handbook, copies of which have been supplied gratis to the headquarters of the various ex Service men's associations The handbook is now being placed on sale, and the local branches will thus be enabled to obtain copies for the information of their members

Mr **RUPERT GWYNNE** asked the Pensions Minister whether he could see his way to issue instructions for extra clothing and bedding to be given from time to time to all ex Service men certified to be suffering from tuberculosis instead of providing it on loan in certain cases —Major **TRYON** replied Where open air home treatment is ordered extra blankets which are certified to be necessary are supplied, but not on loan, nor is the cost recovered Extra clothing is provided as an incident of treatment and not in supplementation of pension, but in certain cases men have expressed the wish to purchase clothing on the termination of treatment, and the question whether this would be practicable is being considered

THURSDAY, APRIL 29TH

Insanitary Pensions Offices at Hastings

Mr **JOHN DAVISON** asked the Pensions Ministry whether he had received any complaints from the staff of the Hastings War Pensions Committee and Medical Referees protesting against the insanitary condition of the offices occupied by that staff and committee, whether he was aware that the medical referees who had held examinations of disabled men in the building unanimously condemned it on account of the unhealthy atmosphere, and on some occasions refused on that account to examine men suffering from open wounds, that these premises were for some years occupied by a department of the Corporation, but that, in consequence of excessive absences through sickness of the members of their staff, the Corporation decided to vacate them, and whether, in view of the unsuitability of these premises as offices and their general unhygienic condition, he would make inquiries into the matter, with a view to securing accommodation in a more healthy situation —Major **TRYON** replied The answer to the first part of the question is in the affirmative The suitability of the accommodation now in occupation by the Hastings War Pensions Committee has been under the consideration of the First Commissioner of Works, who is, I understand, endeavouring to secure other accommodation

MONDAY, MAY 3RD

Orthopædic Cases in Birmingham

Mr **HALLAS** asked the Minister of Health whether he was aware that the Discharged Soldiers' Committee of the Citizens' Committee of Birmingham was finding difficulty in dealing with orthopædic cases in consequence of the massage staff being too small, and whether he could provide the necessary relief —Major **TRYON** (Parliamentary Secretary to the Ministry of Pensions) replied There are a number of vacancies in the Ministry of Pensions Massage Service, but it is expected that these will shortly be filled The necessary additions to the staff at Birmingham will be made as soon as possible

Blind Members of Advisory Blind Committees

Viscountess **ASTOR** asked the Minister of Health whether instructions had been issued to all local Advisory Blind Committees to have among their members one blind person elected as a representative of the blind in the committee's area, and whether, if a local committee failed to comply with these instructions, or, while appointing a blind representative, failed to summon him to meetings of the committee, any steps could be taken by the Minister to enforce his wishes on the local committee —Dr **ADDISON** replied In reply to the first part of the question I gave instructions, on the advice of the Central Advisory Committee, that wherever practicable vacancies occurring in these local committees should be filled by blind persons until at least one third of the committee (excluding representatives from local authorities) were blind persons, and this proportion has not been reached in nearly all cases As regards the latter part of the question, the final appointment of members rests with me, and if the honourable Member will furnish me with particulars of any case in which a person so appointed has not been summoned to meetings I will have this matter looked into and dealt with.

TUESDAY, MAY 4TH.

Foreign Service Roster for Medical Officers

Lieutenant Colonel **BUCKLEY** asked the Secretary for War and Air if he would state what method of selection was adopted in detailing Royal Army Medical Corps officers for duty in India, whether a roster of previous service at home was maintained, and whether consideration was given to service in the theatres of war in detailing officers for India —Sir A **WILLIAMSON** (Financial Secretary to the War Office) replied A foreign service roster for officers of the Royal Army Medical Corps is kept Officers are detailed for service in garrisons overseas in accordance with this roster except in the case of any officer who, on account of special qualifications which he may possess, is required for special duty in the United Kingdom When an officer who has completed a tour of service in India again becomes due for foreign service every endeavour is made to post him to a colony, but this must necessarily depend on the demands for reinforcements and numbers of officers available With regard to the last part of the question, due consideration is given to service in theatres of war other than France and Italy

Medical Men on Sessional Engagements

Mr **ROBERT YOUNG** asked the Pensions Minister if he would state the number of pensioned retired regular naval and military medical men employed by the Ministry on a sessional basis besides those employed at a salary, how many sessions could be put in in a day, whether this was often the most lucrative method of payment for the aforesaid medical men, and whether, on account of the shortage of work, many demobilised civilian doctors were only getting three or four sessions per week which in many cases represented their whole income —Major **TRYON** replied: The number of retired regular officers employed by the Ministry on a sessional basis who are drawing pensions is 152, being 5 per cent of the total number of medical men so employed The maximum number of sessions is 11 per week, but owing to the number of medical men available for the work the average number of sessions per week which can be given to each man is considerably less

Dangerous Drugs Bill

Mr **SHORTT** (Home Secretary) introduced a Bill to regulate the importation, exportation, manufacture sale and use of opium and other dangerous drugs, which was read a first time

Medical News.

University of Cambridge.—At examinations for medical and surgical degrees held in Easter term the following candidates were successful:—

Part II., Pharmacology and General Pathology.—J. C. Ainsworth Davis, Christ's; L. W. Batten, Sidney Sussex; P. J. Briggs, Christ's; E. B. Brooke, Caius; A. W. Brown, Emmanuel; G. H. Caiger, Caius; M. T. Clegg, Jesus; J. R. A. Davies, Clare; J. G. Drew and G. E. Dyas, Caius; F. W. Furniss, Downing; H. J. H. Hendley, Caius; R. A. Highmoor, Clare; F. D. Howitt, Trinity; J. D. Legge Currie, Clare; W. B. A. Lewis, Christ's; G. S. Lund, St. John's; T. K. Maclachlan, Pembroke; F. H. Mather, Sidney Sussex; S. M. Milner, King's; O. G. Misquith, Christ's; R. W. Nichol, Caius; C. C. Okell, St. John's; C. P. Oliver, Caius; P. Richardson, Christ's; F. W. Roques, Clare; D. G. Sharp, Christ's; T. H. Sims, Pembroke; L. V. Snowman, Downing; C. G. Taylor, non-collegiate; R. H. White, King's; L. C. Whitworth, Downing; and R. N. P. Wilson, Pembroke.

Royal College of Physicians of London.—An ordinary Comitia of the Royal College of Physicians of London was held on April 29th, the President, Sir Norman Moore, being in the chair.—The President announced the appointment of Professor C. S. Sherrington as the representative of the College on the committee being formed to consider a memorial to the late Professor Sir William Osler. —The following were admitted to the *Membership* after having passed the required examinations: Dr. R. A. Bennett, Dr. F. B. Chavasse, Dr. T. F. Cotton, Dr. J. A. Drake, Dr. A. W. M. Ellis, Dr. F. R. Fraser, Dr. J. Gatt, Dr. Mary E. Harding, Dr. H. W. Hills, Dr. G. J. Langley, Dr. E. L. W. Mandel, Dr. E. Mapother, Dr. H. B. Russell, Dr. Evelyn D. Scott, Dr. H. S. Stannus, Dr. Margaret G. Thackrah, and Dr. R. H. Wilshaw Licences to practise physic were granted to 70 candidates who had passed the necessary examinations and conformed to the by-laws and regulations.—The following were elected to the *Fellowship* on the nomination of the Council: Dr. W. F. Menzies, Dr. J. G. Forbes, Dr. W. M. Robson, Dr. S. E. Dore, Dr. G. B. Price, Dr. E. L. Holland, Dr. A. Ramsbottom, Dr. A. S. Woodwark, Dr. F. G. Crookshank, Dr. A. C. D. Firth, Dr. N. Mutch, Dr. F. M. R. Walshe, Dr. G. Graham, and Dr. G. E. Beaumont.—The resignation of his membership by Dr. J. W. Springthorpe was accepted.—Dr. John Fawcett and Sir Wilmot Herringham were appointed as representatives of the College on the Senate of the University of London in place of Dr. Sidney Martin and Sir Seymour Sharkey, resigned.

Royal Colleges of Physicians of London and Surgeons of England.—At the Final Examination of the Conjoint Board, held from April 6th to 22nd, the following candidates were approved in the undermentioned subjects:—

Medicine.—A. N. Aitken, Rush Med. Coll.; Kathleen Ardell, Royal Free; M. Bharatan, Madras; S. Blackman, London; J. H. Blair, Queen's Univ.; A. B. Bratton, Cambridge and London; C. H. Bulcock, St. Bart.'s; Joan Katherine Somerville Cave, Royal Free; G. W. Cheater, Charing Cross; H. R. Chibber, Liverpool; Florence Edith Coombes, Royal Free; P. Couacoud, Guy's; F. C. Cozens, Cambridge and St. Bart.'s; F. W. Crook, Guy's; H. A. Crowther, Cambridge and Guy's; K. V. Deakin, Manchester; M. A. Distaso, Bristol and Cardiff; W. D. Doherty, Cambridge and Guy's; T. A. J. Duff, Toronto; Georgiana May Duthie, Manchester; J. H. France, Westminster; Blanche Sutton Gardner, Royal Free; A. G. D. Gavin, Cambridge and St. Thomas's; A. D. Gill, Birmingham; C. I. C. Gill, Cambridge and Guy's; G. E. Hayward, Manchester; F. Heber, London; Florence Janetta Humphreys, Westminster; Ruby Inkster, Univ. Coll.; H. V. Jackson, Bristol; Doris Eleanor Parker Jolly, King's Coll.; S. G. Jones and T. M. Jones, Liverpool; T. T. Jones, Manchester; Dorothy Maud Kemp, Royal Free; Doris Gertrude Knowles, St. George's; J. N. Laing, Manchester and St. Bart.'s; A. Leigh, Manchester; Mary Alice McHugh, Liverpool; L. B. Maxwell, St. Thomas's; G. S. Mitchell, Westminster; Annie Agnes Muir, Liverpool; B. Nanavati, Bombay and London; M. Nurick, London; Marjorie Pierce, Royal Free; Mary Colegrave Prideaux, St. Mary's; M. H. Renall, St. Bart.'s; Edith Mary Seward, Liverpool; J. V. Sparks, Cambridge and St. Bart.'s; P. Steinberg, London; C. J. Thomas, St. Thomas's; F. A. van Coller, Manchester; Nellie Wall, Liverpool; Helena Jane Webster, Westminster; A. D. Whitelaw, St. Thomas's; Dorothea Compston Wigfield, Royal Free; and F. B. Yonge, Middlesex.

Vintner, St. Bart.'s; and W. C. S. Wood, King's Coll.

London School of Tropical Medicine.—The following candidates passed the examination held at the termination of the sixty-second session (February-April, 1920):—

*H. E. Whittingham (Duncan Medal), *A. K. Cosgrave, *A. Khalik, *E. J. Wood, *E. Forrester-Paton, J. Fanstone, E. G. Mack, W. P. Hogg, J. S. Armstrong, J. R. C. Stephens, M. Wong, G. A. S. Madgwick, G. A. Frendo, C. Basile, M. Jackson, E. U. MacWilliam, N. Nedergaard, H. R. Dive, J. S. Crollus, J. Gray, A. Y. Cantin, D. Sohokman, and C. H. Brangwin.

* With distinction.

Royal College of Physicians of Edinburgh.—The George Alexander Gibson Memorial lecture will be delivered in two parts in the hall of the College on May 10th and 12th, at 5 P.M. each day, by Dr. William Russell. The subject chosen is the Sphygmomanometer in Practical Medicine. The first lecture will deal with the problem and the second with illustrations and interpretations.

University of London: University College.—A public lecture on Greek Science and Modern Science: A Comparison and a Contrast, will be delivered at 5.30 P.M. on May 12th by Dr. Charles Singer, Sir Robert Hadfield in the chair.

The University of Oxford has received an offer from Mr. Edward Whitley of £10,000 towards the endowment of a Professorship of Biochemistry, and a donation of £5000 from the British Dyestuffs Corporation, Ltd., towards the cost of extending the organic chemical laboratory.

University of Birmingham.—A course of post-graduate instruction is being given in the Medical Faculty, Edmund-street, and at the associated hospitals, beginning July 5th to 17th. The course will comprise sections of medicine, surgery, pathology and bacteriology, obstetrics and gynæcology, diseases of children, ophthalmology, diseases of ear and throat, radiology, electrical treatment, anatomy, and physiology. The fee for admission to the lectures and clinical demonstrations in each section is 1 guinea. Further particulars from the clerk to the Clinical Board, University, Edmund-street, Birmingham.

University of Manchester Appeal.—Another novel proposal in connexion with this appeal has been launched by the council of the University, who have decided that for every £5000 subscribed a free studentship shall be created, so that every private donor, town, district, or trade union subscribing this amount shall have the right to nominate a free scholar at the University. The importance of the step is that the new Education Act provides for the education of every boy and girl in the country up to matriculation standard, and if this decision of the University of Manchester is carried to its logical conclusion the endowment of free university education is accomplished and an undoubted step taken towards the democratisation of the University.

INDIAN MEDICAL SERVICE DINNER —The annual dinner of the Indian Medical Service will be held at the Trocadero on Tuesday, June 8th, at 7 45 P M , Major General G T A Harris, C S I , in the chair Tickets and all particulars may be obtained from the joint honorary secretary, Colonel J J Pratt, I M S (retd), 63, Addison road, London, W 14

MEDICAL SOCIETY OF LONDON —The Annual Oration will be given at 11, Chandos street Cavendish square, London, W , *on Monday May 10th* at 9 P M , by Lieutenant Colonel Sir D'Arcy Power, on the Rev John Ward and Medicine The President, Mr V Warren Low, will hold a reception at 8 30 P M , and during the evening will present the Fothergillian gold medal to Sir Leonard Rogers

ST THOMAS'S HOSPITAL POST GRADUATE INSTRUCTION IN VENEREAL DISEASES —A course of instruction in venereal diseases is being given on Thursdays at 3 P M , commencing May 20th, and lasting for 12 weeks Colonel L W Harrison will lecture on the Principles of Diagnosis and Treatment, and practical instruction will include the examination of patients, *microscopical* work, and the administration of anti syphilitic remedies, on a specified day in each week to be arranged Further particulars from the Medical Secretary, St Thomas s Hospital, London, S E 1

SMALL POX IN LONDON —Some of the small pox cases which have occurred in and around London during the past few weeks having remained undiscovered for a considerable time after the onset, the London County Council calls attention to the arrangements under which in doubtful cases the certifying practitioner confers with the medical officer of health of his borough Should a further opinion be required on application to the Public Health Department, at 2, Savoy hill, London, W C 2 (Tel No Gerrard 3641), the services of Dr W McC Wanklyn will be available

WEST LONDON MEDICO CHIRURGICAL SOCIETY DINNER —At a dinner of the West London Medico Chirurgical Society, held in the Wharncliffe Rooms on April 29th, the society's triennial gold medal was presented to Mr G E Gask, the other proposed recipient, Dr T R Elliott, being unavoidably absent Mr Herbert Chambers, the President, was in the chair, and a distinguished gathering included Dr Phineas Abraham, the founder of the medal The toast of "The Imperial Forces," coupled with the names of Sir Robert Hill and Sir John Goodwin, was proposed by Sir Robert Armstrong-Jones Summing up the benefits to laymen from the medical research and practice of the war, he spoke of the advance in the surgery of the brain, pleural cavity, fractures of the thigh and face, and of the importance of the Carrel Dakin methods , he alluded also to the treatment without certification of nervous and mental diseases and psycho neuroses All this work had been made possible by the helpful cooperation of the administrative heads of the medical departments In their replies both Directors General spoke with appreciation of the services of the civil profession in the war and of the important work done at the West London Hospital post graduate courses, Sir John Goodwin testifying to the great help which he had himself received there The toast of "The West London Medico Chirurgical Society " was proposed by Sir William Hale White, who in an interesting reminiscent speech recalled the work of eminent medical men connected with the society, including Sir William Jenner, Sir James Paget, and Sir William Osler In reply, Mr Herbert Chambers referred to the labours of the late Charles Keetley in founding the society This was the fourth occasion, he said on which the triennial medals founded for special heroism in the field or distinguished services to medical science had been given The selection committee, with the coöperation of Sir Humphry Rolleston and Sir Anthony Bowlby, had decided to give the medal this year for some achievement arising out of the war in the cause of medical science A remarkable advance in the surgery of gunshot wounds of the thorax due to the pioneer work of Dr Elliott, had enabled Mr Gask, who was the first member of the society to receive the medal, to perform a brilliant operation Mr Gask thanked the donors for the honour conferred upon him, but deprecated praise accorded to Dr Elliott and himself to the exclusion of others The work was the outcome of the labours of a variety of men in the British as well as in the French army, and was dependent also on the harmonious coöperation between physicians and surgeons Particularly credit was due to Dr K D Wilkinson, as well as to the help given by the administrative departments The toast of "Kindred Societies and Guests" was proposed by the Mayor of Kensington (Dr A J Rice-Oxley), Mr V Warren Low (President of the Medical Society of London) and Dr Leonard Williams responding, and a pleasant evening was brought to a close by a vote of thanks to the chairman proposed by Sir D'Arcy Power

ABERDEEN UNIVERSITY CLUB —The half yearly dinner is to be held at the Criterion Restaurant on Thursday, May 20th, at 7 30 P M , preceded by the annual general meeting (6 30 P M) All communications should be addressed to Dr W A Milligan, 11, Upper Brook street, W 1, who will be pleased to receive names of intending members

THE Congrès Français d Oto Rhino Laryngologie will be held in Paris next week from May 10th to 13th, and a large number of British specialists are going to the meeting For the meeting of *the Royal Institute of Public Health in* Brussels the hotels are already largely engaged from May 20th to 24th

PHYSIOLOGICAL CONGRESS AT PARIS —This Congress which met at Groningen in the year before the war had fixed on Paris as the place for its next meeting and had nominated *Professor* Charles Richet *Professor of Physiology* in the University of Paris as its president Not till this year, however, has it been possible for a meeting to be held and it will take place from July 16th to 20th at Paris Professor E Gley (Sorbonne 1, Rue Victor Cousin) is the secretary , the subscription has been fixed at 35 francs and a list of hotels available for members has been issued, the prices of a *lit* varying from 6-9 to 20-30 francs

NATIONAL COUNCIL FOR COMBATING VENEREAL DISEASES —Lord Sydenham *having notified the Executive* Committee of the Council that he would soon have to tender his resignation, Lord Gorrell has been nominated as his successor, while as a mark of recognition of Lord Sydenham s services it is proposed to entertain him at a farewell dinner

VENEREAL PREVENTION IN PORTSMOUTH —The Borough Council has adopted the recommendation of its Health and Housing Committee to take steps to spread among the male population of the borough a knowledge of the means of self *disinfection* as *indicated* in Dr A. Mearns Fraser's report Before the sitting was held at which this *decision* was taken a *representative gathering* of many interests met at the mayor's invitation to hear Dr Fraser expound his scheme In the ensuing discussion the consensus of opinion appeared in favour of the municipality popularising the means of self disinfection, although no formal vote was taken At the same time a number of voluntary agencies agreed to take the opportunity of a simultaneous ' chastity campaign "

THE UNIVERSITY COLSTON SOCIETY, BRISTOL —The society's annual dinner will be held shortly, when the guest of the evening will be Lord Moulton Alderman Frank Sheppard has accepted the office of President for 1921 The Bishop of Bristol, who is this year s President of the Colston Society, has issued an appeal for funds for research No collection has been made since 1917 when only £275 was raised, and it is hoped that the Bishop s appeal will bring in a far larger collection than has ever been amassed before

THE LATE DR W K FYFFE, OF WELLINGTON, N Z —William Kington Fyffe B A M B Camb , M R C P Lond who died on April 23rd at Wellington after an operation, was eldest son of the late Deputy Surgeon General W J Fyffe He studied at Cambridge and St George s Hospital, London where he became house physician and medical registrar and he was for a time assistant *physician* and pathologist to the Victoria Park Chest Hospital During the war he served as medical officer with the 4th New Zealand contingent at Gallipoli

A MEDICAL AID SOCIETY IN SOUTH WALES —The employees of the Windsor Colliery at Abertridwr desire to alter the present arrangements for colliery medical service They desire to become a registered society for providing medical aid The proposed society would engage whole-time doctors to provide medical attendance *It would also* embrace in its scope of activities the providing of drugs hospital and nursing benefits, expert treatment by specialists when needed *special nourishment* optical and dental treatment, artificial limbs and surgical appliances and spectacles at cost price Three medical officers are now asked for, a chief officer to live at Abertridwr and to receive £1000 per annum, with, in addition a house, coal, light and expenses in connexion with his duties such as a motor conveyance , a *second* to live at Caerphilly and receive £800 with extras as above, and a third at Senghenydd at a salary of £700 with the same extras Medical attendance on the families of the workers appears to be required as well as on the miners, of whom there are rather less than 2000 at this colliery , and since each worker would have on the average three dependents the total population to be served by the three medical officers would be about 8000 The society is to be managed by a committee of nine underground workers five surface workers and three officials No suggestion appears that any profit would be made by the society or that the services of the medical officers would in any way be exploited for gain but professional difficulties may be anticipated in regard to working the scheme

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee, held on Tuesday, April 13th, 27 cases were considered, and £374 9*s.* voted to 24 of the applicants. The following is a summary of some of the cases relieved:—

Widow, aged 34, of M.B. Edin. who practised in N. Nigeria and with the Booth Line and died in December, 1919. Was left entirely unprovided for, her only income being £30 from investments, and she has a child, aged 4 months, which at present she cannot leave to earn her own living. Pays £2 2*s.* a week for board and lodging. Voted £18 in two instalments.—Widow, aged 38, of M.R.C.S. Eng. who practised at Newcastle, Staffs., and died in February, 1920. Was left with four children, ages 4 to 1 year, and has no income whatever. At present the guardians are allowing her to live in the resident medical officer's house, where she lived previously. Voted £18 in two instalments.—Widow, aged 43, of L.S.A. Lond. who practised at Bolton-on-Dearne, and died in October, 1919. Only income £70 from investments. Has four children, the eldest girl, aged 16, training as a shorthand typist; the younger children at school. Cannot manage owing to the high cost of living. Voted £18 in 12 instalments, and a special grant of £10.—Daughter, aged 60, of M.R.C.S. Eng. who practised at Battle, Sussex, and died in 1873. She has no income, and lives with her sister, who lets rooms when possible. Suffers from chronic rheumatism. Relieved 35 times, £290. Voted £18 in 12 instalments.—Daughter, aged 58, of M.R.C.S. Eng. who practised at Newport, Mon., and died in 1892. Was left totally unprovided for, and her only income is £21 from another charity. Pays 7*s.* 6*d.* a week rent. Suffers from ill-health. Cannot manage owing to the high cost of living. Relieved nine times, £117. Voted £18 in 12 instalments.—Widow, aged 36, of M.R.C.S. Eng. who practised at Witney and died in 1918. She receives £300 from investments, but she pays £75 in rent. She has three children, ages 12, 10, and 9, all at school, and she requires clothes for the children. Relieved twice, £10. Voted £2, and the case referred to the Guild.—Widow, aged 58, of M.R.C.S. Eng. who practised in Devonshire and died in 1914. Was left entirely without means, with one daughter, now aged 26, who is a children's nurse. Applicant has been earning £30 a year as a housekeeper, but is now ill and out of employment. Staying with friends. Relieved seven times, £64. Voted £18 in 12 instalments.—M.R.C.S. Eng., aged 83, widower, who practised at Hastings. Only income a pension of £100. Suffers from ill-health. Has one daughter, who looks after applicant. Rent and rates £39, part of which is paid by friends. Relieved once, £26. Voted £26 in 12 instalments.—Widow, aged 65, of M.B. Glag. who practised at Birkenhead and died in 1885. She receives £20 from another charity and £15 from a lodger. Does occasional needlework. Has three children who help all they can. Suffers from neuritis and heart trouble. Rent and rates £30. Cannot manage owing to the high cost of living. Relieved ten times, £120. Voted £12 in 12 instalments.—Daughter, aged 52, of M.R.C.S. Eng. who practised in Bombay and died in 1873. Has taken charge of a mental case for 14 years, for which she receives £1 a week. Rent and rates £16 a year. The high cost of living makes it impossible for her to manage. Relieved eight times, £93. Voted £18 in 12 instalments.

Subscriptions may be sent to the honorary treasurer, Sir Charters Symonds, at 11, Chandos-street, Cavendish-square, London, W.1.

LIVERPOOL MEDICAL INSTITUTION.—At a meeting of the Pathological Section of this society held on April 15th, Dr. J. F. Gemmell, the President, in the chair, Mr. F. C. Lewis read a note on the Standardisation of the Blood-cell Suspension in Complement-fixation Tests. He demonstrated his thesis in vitro, and laid emphasis on the fact that different workers used suspensions of different strengths; and further, that the method generally adopted for making the suspension led to irregularities in the strength. It was suggested that variations in the result of Wassermann tests applied to the same serum could, other factors being equal, be explained on the assumption of a variable minimum hæmolytic dose of complement. A plea was made for the use of a uniform and gravimetric suspension in order to ensure that the term "minimum hæmolytic dose of complement" was common to all laboratories.—Mr. John T. Morrison contributed a short paper on Diseases of the Male Breast, with Special Reference to Chronic Mastitis. The general similarity to diseases of the female breast was pointed out and a brief description given of the malformations, acute inflammations, granulomata and neoplasms affecting the gland. The condition, unsatisfactorily termed "gynecomastia," was discussed in detail. Histological reports were very few in number, but none confirmed the suggestion that the condition was a true hypertrophy of mammary tissue. On the other hand, there was evidence that a slow, quiet inflammatory process was at work in most instances. In cases of frankly chronic inflammation, the breast, or a nodule within it, could be felt as a firm well-defined tender mass; axillary adenitis might be present, but suppuration was rare. Histologically there was an increased formation of fibrous tissue with sometimes, in addition, an increase in the number of ducts; inflammatory reaction was noted at this latter site. It was recommended that cases which did not react to rest and the application of heat should be excised and examined microscopically. The suggestion was made that the lactiferous ducts, or their accompanying lymphatics, were the path of entry of the causal factor. The paper was freely illustrated by lantern slides.

PROPOSED MEDICAL INSTITUTE IN NEWCASTLE.—The establishment of a medical institute and club for the North of England has been advanced a further stage. Of the £10,000 required for the purchase and equipment of a suitable building, £5000 was already promised by Dr. J. W. Smith, of Ryton, in memory of his son (see THE LANCET, 1919, i., 1098). The building is to include a library and rooms for meetings, a restaurant, billiard, smoking, and card rooms, and a few bedrooms for members are to be provided. The combination of the conveniences of a club with facilities for obtaining technical literature in a meeting place for doctors should prove popular, and the appeal of the committee for promises of membership for a period of five years at £2 2*s.* a year should receive a wide response. Medical men of the North of England are asked also to subscribe £10 each towards the initial expenses. The secretary of the committee is Dr. J. Don, 1, Grove-street, Newcastle-on-Tyne.

NATIONAL BABY WEEK COUNCIL.—The Council has issued a leaflet (No. 8) entitled "Notes for Speakers on Child Welfare, 1920," which should prove useful to those for whom it is intended. The leaflet includes notes on child mortality, on the requirements of healthy babyhood, widows' pensions, and on a few of the ways in which the ordinary lay citizen can promote the aims of the Council. The provision of reliable statistics in simple form will enable many busy speakers to be more concrete and definite in their statements without fear of inaccuracy, and should thus add greatly to the effect of their appeals.

A meeting of the Council will be held at Armitage Hall, 224, Great Portland-street, London, W., on Tuesday next, May 11th, at 3 P.M., Viscount Astor in the chair, when Dr. Eric Pritchard will present the executive committee's report and scheme for this year's campaign, and Dr. Helen Swatman will give an address on the Development of Infant Welfare and Antenatal Work in Rural Districts, to be followed by a discussion. Mrs. H. A. L. Fisher will speak on the Problem of the Unmarried Mother and her Child, and Mr. T. Vivian Rees on the Children's Era. The meeting will be open to non-members of the Council by ticket, which may be obtained free on application to the secretary at 27A, Cavendish-square, London, W.1.

MANCHESTER ROYAL INFIRMARY *POST* GRADUATE CLINIC

TUESDAY, May 11th —4 30 P M, Lecture —Dr D E Core Hysteria and Certain Indications for its Treatment

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS at the two Hospitals alternately

THURSDAY, May 13th —4.30 P M, Dr Dyson Tuberculosis of the Skin (At Salford Royal Hospital)

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column are invited to forward to THE LANCET *Office, directed to the Sub Editor, not later than 9 o'clock on the Thursday morning of each week such information for gratuitous publication*

BOURNE, G M B Lond, M R C P, has been appointed Physician to the East London Hospital for Children, Shadwell

DYSON, W, O B E, M D, Honorary Dermatologist to the Manchester Royal Infirmary

HERZFELD, GERTRUDE M A, M B, Ch B, Junior Surgeon to the Edinburgh Hospital for Women and Children

POLLARD, Sir G H, M D Edin, Clinical Assistant at St John's Hospital for Diseases of the Skin

VINING, C W M D, B S Lond, M R C P, D P H, Assistant Physician in Charge of Children's Department, General Infirmary, Leeds

Certifying Surgeons under the Factory and Workshop Acts **SPENCE, D L**, M R C S, L R C P Lond (Melksham) **STEELL J W G**, M R C S, L R C P (Youlgreave), **LLOYD, W A T**, L S A (Llandilo)

Vacancies.

For further information refer to the advertisement columns

Barnsley, Beckett Hospital —Jun H S £200

Battersea Borough Council —Asst M O H £700

Birkenhead Borough Hospital —Jun H S £200

Birmingham General Dispensary —Res M O £400

Bradford Children's Hospital —H S £180

Bradford City Education Committee —Asst School M O £600

Bury County Borough —Asst M O H, &c £600

Bury St Edmund's, West Suffolk General Hospital —Res H S £175

Buxton, Derbyshire Devonshire Hospital for Rheumatism and Allied Diseases —H P £250

Cancer Hospital Fulham road, S W —Three Anæsthetists

Canning Town Women's Settlement Hospital, Balaam-street, Plaistow, E —Hon Visiting S

Chester County Asylum —Third Asst M O £350

Colchester, Severalls Mental Hospital —Fourth Asst M O £510

Colchester, Royal Eastern Counties Institution for Idiots Imbeciles, and the Feeble-Minded —M O £300

Coventry Education Committee —Two Sch Dents £400

Cupar-Fife, Fife and Kinross Joint Sanatorium Board, Glenlomond Sanatorium —Asst Res M O £300

Derby County Borough —Asst Tuberc O £500

Derby, Derbyshire Royal Infirmary —Oph H S £200

Dr Barnardo's Homes, 18 26, Stepney Causeway E —Sen M O

Durham University —Asst in the Dept of Bacteriology £600

Freemasons Hospital and Nursing Home, 237, Fulham road, S W —Res M O £250

Galway, University College —Professorships of Anat and Phys

Great Northern Central Hospital, Holloway N —H S £150

Greenwich Union Infirmary, Vanbrugh hill, East Greenwich, S E —Asst Med Supt £300

Guildford, Royal Surrey County Hospital —Third H S £150

Halifax Royal Infirmary —H S £200

Hants Enham Village Centre for Disabled Ex Service Men, near Andover,—Asst Med Director £500

Hindley Urban District Council —M O H and School M O £850

Hull Royal Infirmary —Senr H S £200 Also Cas H S £150

Ilford Urban District Council —Dent S £500

Isle of Wight County Asylum —Asst M O £300

King's College Hospital, Denmark Hill S E —Bacteriologist

Kingston, Ont, Queen's University —Prof of Clin Surgery $5000 Prof of Path, Prof of Anat, and Prof of Pharm $3500 each Prof of Prev Med and Pub Health $3000 Asst Prof of Phys $2000

Leeds City —Asst M O for Maternity and Child Welfare £500

Leeds Public Dispensary —Res M O £200

Liverpool, Royal Southern Hospital —Cas O £150

Liverpool Stanley Hospital —H S's £150

London Lock Hospital Dean-street, Oxford street W, and 253 Harrow-road Paddington, W —Pathologist £500

Macclesfield Cheshire County Asylum Parkside —Asst M O £350

Maidstone Kent County Ophthalmic Hospital —H S £250

Manchester, Ancoats Hospital —Hon Con Oph S and Hon P

Manchester Children's Hospital, Gartside-street, Manchester —Asst M O £200

Manchester Hospital for Consumption and Diseases of the Throat and Chest, Bowdon Cheshire —Res M O £350

Manchester Royal Infirmary —Second H S to Special Departments £25 for first six months and £50 for second

Manchester, St Mary's Hospitals for Women and Children —Two H S s for Maternity Hospital £100

Middlesbrough, North Ormesby Hospital —Asst H S £200

Middlesbrough, North Riding Infirmary —Hon S

Middlesex County Council —Female Asst M O £500

Midlothian, Saughton Hall Private Asylum —Med Supt

Miller General Hospital for South East London, Greenwich road S E —Hon Asst Ophth S

Montrose Royal Asylum —Asst M O £300

Newcastle-upon Tyne, Hospital for Sick Children —Jun Res M O £200

Newcastle-upon Tyne Royal Victoria Infirmary —Anæsth Also Refractionist £100

Norfolk County —Tuberc O £600

Northampton General Hospital —H S £200

Norwich, Norfolk and Norwich Hospital —H P and Two H S s £200.

Nottingham General Hospital —Cas H S £200

Oldham Royal Infirmary —Third H S £200

Portsmouth Royal Hospital.—H.S. £150.
Preston and County of Lancaster Royal Infirmary.—H.S. £180.
Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Asst. Res. M.O. £50.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Hon. Anæsth. £25. Also H.S. £100.
Rochester, Kent, St. Bartholomew's Hospital.—Jun. Res. M.O. £150.
Rotherham Hospital.—Jun. H.S. £150.
Royal Chest Hospital, City-road, E.C.—M.O. in X Ray Dept. 25 gs. Also Clin. Assts. Also H.P. £120.
Royal Ear Hospital, Dean-street, Soho, W.—H.S.
Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £200. Also Cas. O. £100. Also Two H.S.'s. £50.
St. Mary's Hospital for Women and Children, Plaistow, London, E.—Res. M.O. £200.
St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—Jun. H.S. £75.
Seamen's Hospital Society, Hospital for Tropical Diseases, Endsleigh-gardens, N.W.—H.P. £100.
Sheffield Royal Hospital.—Cas. O. and Asst. Cas. O. £150 each.
Sheffield Royal Infirmary.—H.P. and H.S. £150 each.
Sleaford, Kesteven County Asylum, near Sleaford, Lincolnshire.—Asst. M.O. £350.
outhampton County Borough.—Sch. Dent. £500.
South London Hospital for Women, South Side, Clapham Common, S.W.—Female Asst. Path.
Stamford, Rutland, and General Infirmary, Stamford.—H.S. £200.
Stockport Infirmary.—Jun. Res. M.O. £200.
Stroud General Hospital.—H.S. £200.
Surrey Dispensary, Southwark, S.E.—Res. M.O. £300.
Torquay Local Education Authority.—Asst. Sch. M.O. and Deputy M.O.H. £500.
Union of South Africa.—Asst. Health O. £900. Also Two Med. Inspectors, £850 each. Also Asst. Path. £750. Also Government Med. and Port Health O. £750.
University of London, St. Mary's Hospital Medical School.—Univ. Chair of Physiology. £900.
Warwickshire County Council.—Assistant County M.O.H. £500.
Weir Hospital, Grove-road, Balham, S.W.—Res. M.O. £150. Also Hon. Visiting P.'s and S.'s, Radio., and Anæsth.'s.
Wells Asylum, Somerset.—Sen. Asst. M.O. £450.
West Bromwich and District Hospital.—Res. H.S. £200.
West Ham Union.—Two Specialist Consultants. £150.
West London Hospital, Hammersmith, W.—H.P. and H.S. Also Surg. Dent. or Asst. Surg. Dent.
Western Dispensary, 38, Rochester-row, S.W.—Vacancy on Attending Med. Staff.
Whitehaven and West Cumberland Infirmary.—Res. H.S. £180.
Wigan Infirmary.—Senior H.S. £250.
Wolverhampton and Staffordshire General Hospital.—H.S. £200.
Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £300.
Worthing, West Sussex and Chichester Joint Education Committee.—Asst. Sch. M.O. £500.

The Home Secretary gives notice of a vacancy for a Specialist Medical Referee under the Workmen's Compensation Act, 1906, for Ophthalmic cases in County Court Circuit No. 6. Applications should reach the Private Secretary, Home Office, not later than May 26th, 1920.

The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Ballindalloch, Cardenden, Ellesmere, and at Leicester (West).

Births, Marriages, and Deaths.

BIRTHS.

ALLEN.—On April 30th, at Upper Richmond-road, Putney, the wife of Captain W. B. Allen, V.C., D.S.O., M.C., R.A.M.C., of a daughter.

CARROLL.—On May 1st, at St. Petersburg-place, W., the wife of Charles Herbert Carroll, M.R.C.S., L.R.C.P., of a daughter.

COX.—On April 30th, at a nursing home, Manchester, the wife of George Lissant Cox, M.D. Cantab., of a daughter.

MCMULLAN.—On April 30th, the wife of George McMullan, M.D., F.R.C.S.E., Wallingford, Berks, of a son.

MAXWELL.—On April 26th, at St. Ann's, Kirkcaldy, N.B., the wife of James Maxwell, M.D., of a daughter.

RAINEY.—On May 2nd, at Wakefield House, Compton-street, Eastbourne, the wife of E. H. Rainey, F.R.C.S., of a daughter.

MARRIAGES.

GOODWIN—ADAMS.—On April 29th, at St. Jude's Church, Southsea, Surgeon Lieutenant-Commander Ernest St. George Sagar Goodwin, M.A., M.B., R.N., to Ida Dorothy, younger daughter of Engineer Captain W. H. Adams, R.N., and Mrs. Adams, of Craneswater-avenue, Southsea.

DEATHS.

SPENCER.—On April 7th, at Eastbourne, John Spencer, L.R.C.P. & L.R.C.S. Ed., L.F.P.S. Glasgow, of 347, High Road, Leyton, Essex, aged 60.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

A MATINEE in aid of the Nurses' Home Fund of the Great Northern Hospital, Holloway, will be held at the Palladium on Friday, May 14th, at 2.30 P.M. Her Majesty Queen Alexandra has expressed her hope of being present. Tickets may be obtained from the secretary of the hospital.

BOOKS, ETC., RECEIVED.

Notes, Short Comments, and Answers to Correspondents.

THE INDUSTRIAL SETTLEMENT FOR THE CONSUMPTIVE.

BY P. C. VARRIER JONES, M A. CANTAB, M R C S., L.R C.P. LOND.,
HONORARY MEDICAL OFFICER, PAPWORTH COLONY, CAMBRIDGE
AND
SIR G. SIMS WOODHEAD, K.B E, V D, M D, LL D,
PROFESSOR OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE
FELLOW OF TRINITY HALL, CAMBRIDGE

THE earlier conception of colonies for tuberculous subjects was associated with little more than the prolongation of the period of treatment of the individual. The newer conception of the duties of *after care and colony* committees is based on *the inclusion* of the idea of partial if not complete separation or segregation of the tuberculous patient. The colony idea, then, at first at any rate, connoted no thought for the welfare of the community, it was concerned merely with assuring the benefit of the sick individual.

Communities for the tuberculous will not, however, be such artificial and involuntary segregated bodies as some people would have us believe. Indeed, the village settlement has a two fold justification. It not only offers employment to those who cannot be employed elsewhere, but it affords them relief from the economic pressure of the outside *world*. *Why do we healthy* subjects live and work in the *environment in which we* happen to find ourselves? Unless we are wealthy aristocrats we, all of us, have to work and live where we can earn our living, similarly it will be found that the consumptive will live and work where conditions are favourable for him. It must be clearly understood, however, that the founding of such a community is a problem not so simple as it sounds. Any fantastic idea of acquiring a large tract of land and sending consumptives to live there and fend for themselves as best they can is doomed to failure from the outset. It is only by the most gradual steps that such a *community* can be brought into being and developed.

An Industry for Consumptives

Here we open up *new ground* and *put forward* a *new* idea to which the individual and the national mind will turn and readjust itself. Just as the well to do seek special places and climates for the benefit of *their health*, so—we must get accustomed to the idea—those not so well endowed with worldly gear may with equal propriety seek some place best suited for the prolongation of their life under the most favourable conditions. The only difference *is one of "exchange" and economics*. *To provide the rich* patient with the wherewithal to give in exchange for the amenities of life others work or have worked, while the man ordinarily dependent on his own exertion, having no one to work for him, must himself continue to work. He also can exchange the results of labour—his own—into food and comforts for himself and his family, even if *he cannot* provide for them completely. The village community, or industrial settlement—whatever it is *called*—is *designed to* provide the opportunity for such exchange.

Since a village community cannot be called into being by a *stroke of the pen, it is necessary* to build it up gradually and quietly from the materials ready to hand. Towns and villages are generally called into being by the influx of inhabitants seeking food and work. An industry is started, it matters not what, a population immediately follows and congregates around it. The people are *there for the benefit* of the industry, not the industry *for the benefit of the* people. Why not, whilst following the usual plan as regards the first part of the process, reverse the second and, founding an industry, run it for the benefit of the people? Set up your industry and the people will flock to it, but in this instance let the industry be set up for consumptives, let it be run for their particular and special benefit, and they will come—and stay.

The Principle Involved

Such is the process a *perfectly* rational and feasible one of starting a community for consumptives. The starting of an institution is quite a different matter—the latter is artificial, the crowding together of *members of one sex*—relieving them of all sense of responsibility and of proportion. Men or women remaining for long under an institutional regime are left in conditions in which they lose interest in life and become dependent on others for moral support. A village community must not be a collection of almshouses, filled with pensioners spending their last years dependent on the charity of others. That is quite unnecessary, for these colonists or settlers are neither old nor infirm. Their strength is certainly diminished and their health impaired, but with encouragement and opportunity, both of which should be freely given, they will be able to contribute very materially to their own support and that of their families. The opportunity to work is what is required, and their earnings, together with a *small pension*, will *in most cases* enable them to become self supporting certainly to a much greater extent than were they compelled to enter into competition with the healthy worker in the outside world. All the artificial helps and make believes of an institution should be avoided. Full liberty of conscience and action must be given and also guidance and help in the art of becoming as fully self supporting as possible. The sapping of the moral character of *the man by gifts and doles* should be carefully avoided. The settler must realise that he lives in a world of realities, that there is still a struggle for existence, even if the external winds and conditions are tempered to the shorn lamb. The remaining fraction of the struggle we would certainly not do away with, for it is no less valuable, nay necessary for the formation of character than is the struggle for existence in the outside world. Suitable work is by *no means an unimportant factor in the treatment* of the consumptive, indeed, it must be looked upon as the central pivot of the whole system. It is, however, *the focal* point of great and numerous difficulties. To obtain food a man must work, unless another comes to his assistance. In order therefore, that a consumptive may live he should also work and this he can do if he be given the opportunity and conditions in which to perform the selected tasks *allotted to him*. There is in the consumptive a potential, though a limited, source of energy. That energy can now be made available under known and well defined conditions. Now by continuous observation and research and by a study of various industries, the kind of work and the hours worked, *a knowledge of the conditions of work desirable for a* consumptive has been arrived at. The problem therefore resolves itself into the practicability or otherwise of setting up industries which, when *run by consumptive labour* can be made to return a remunerative rate of wages. Can any means be found whereby the produce of such industry can compete in the ordinary market, for unless a market can be found disaster must quickly ensue. Our outlook must therefore be much wider than that of employing men at a simple occupation at which a little money can be earned. The greater the wages earned *the better the financial position of the consumptive settlers*, the less will be the call upon charity or the State for their upkeep. The greater the proportion of earnings to the subsidy the greater also will be the *man's* own self respect. We must clearly keep in view the important problem of permanent, remunerative industry, playing at a trade must not be countenanced under any circumstances.

The Training of the Industrial Worker

The days of the old craft guilds have unfortunately passed away. In those days a man was a skilled craftsman, and turned out an article at which *he had worked from start to* finish. To day there is no market for the product of such craftsmanship. The machine has revolutionised man's work, and without its aid this work is no longer remunerative. We have only to question the great bulk of the working men *of to day as to their* occupation to learn that they are machinists. *For the most part* there is no special skill required for the job. It is astonishing how completely the workman's faculties may lie dormant during *most of* the operations called for from the machinist, and to this the unrest of the present day may in some measure be attributed. We educate a man's faculties up to a point, we then allow him to go through life without calling *for their use*. It is *obvious* then that when we talk about training a man to be this or that kind of skilled artisan or craftsman, we are literally talking folly, though we may not always realise the fact. *In the factories in large centres*, except in the case of the "*key men*," thorough training does not exist, and, in the sense we know it, is never called for. A man is set to look after a machine, and for this *little technical training or skill* is needed and the instructions given to him are brief and the directions simple. The machine does the work, all the man does or has to do is to set the pace. Such, in brief, is the environment *from which, for* the most part, our patients come, and *their diminished* powers have to be readjusted to their new surroundings. We have no alternative but to take as our model the normal industrial world even though we may have to modify it in *certain details*. We *must* eliminate certain factors which would inevitably make for disaster to the consumptive. *All isolated efforts of training* we are convinced, must inevitably prove futile. Individual labour cannot ensure a turnover by means of which the *consumptive* can compete with the healthy labour of the modern factory, unless we can get a large turnover we cannot provide a remunerative wage. But though the attempt to earn a *good* wage in the open market involves disability and death to the consumptive, we can modify methods and provide special conditions wherein the profits are used to increase his pay. We believe that with perseverance success may be attained in this difficult task even for large numbers. We have, indeed, proved it among small numbers. We had first to realise that the working man of to-day has to be trained in the majority of cases, not as the master of a trade but as a hand in a factory. Having realised this, our task was greatly simplified. It amounted to training him to be a hand. Fortunately he wants nothing more to enable him to earn his living, for our difficulties would certainly be infinitely greater were it necessary to teach each man a skilled trade. As our community grows, however, we have room for another class of worker—the consumptive who is already skilled and who desires other environments and another position. Such an one can always be accommodated in the settlement and his advent is hailed with delight by the colony authorities; for, just as the factories in the outside world employ men in special offices and lay positions, so also the consumptive community has room and employment for all of them. One trade sets in motion another, subsidiary branches soon give evidence of sprouting, and within a short time an office staff is required and develops; a packing department and a designing shop become necessary and make their appearance, and, one after the other, various side lines spring up. It is the knowledge that the concern is alive and progressing, that it can and will employ its hands permanently, that makes for the contentment of mind of the consumptive village settler. The life he leads is as near as possible to the old one to which he had become accustomed. The weekly wage is earned and regularly paid and, finding it possible to live decently and without running into debt, the colonist settles down just as he would have done had he migrated voluntarily from one regular centre of industry to another.

It must not be supposed, however, that a tuberculous community is in all respects like a community of healthy persons. From the psychological point of view the two are very different, and this difference is most marked in the "minor matters of the law." Whether we are brought into closer contact with the workers and their families than would normally be the case in an ordinary community, it is impossible to determine, but on the whole small domestic trials appear to affect the mental outlook of the consumptive to a much greater extent than they affect that of normal individuals. The exaggerated care they take of their health is very evident even to the casual observer. They will run no risks. These characteristics alone supply almost convincing evidence that the results of treatment and residence in a settlement should be infinitely more satisfactory than a system in which patients, after a short residence at a sanatorium, return to their former surroundings.

The Family of the Consumptive.

It may be, indeed it has been, suggested that the village settlement is an expensive method of attaining an end that might be achieved by simpler and less costly means. Is it not possible, it is asked, and would it not be equally effective, to provide workshops in town where, under a special arrangement, these consumptives may work and earn their living? Emphatically, No! The village settlement does much more than provide a job for the consumptive; it also makes provision for his family to be reared in healthy surroundings and under such favourable conditions that their resisting powers may be built up and maintained. At first sight it is not quite evident why this should be the case, for it might appear that to bring a healthy family into a village in which there are more consumptives than are found in an average normal village must increase the risk of infection to the healthy. On consideration, however, this argument is found not to be valid. Let us, for a moment, picture the life and surroundings of a typical and failing consumptive in a town. His working hours being cut down, his wage is also reduced; it follows that the total amount available for the purchase of food for the family is correspondingly low; consequently, the family are underfed, badly clothed, and live in a low-rented house in a poor neighbourhood. The facile descent of the consumptive working man down the social scale is well known, and if lowered resistance plays any part in infection, the members of the family of such a man are in an all too favourable position to contract an infective disease. We have present the two essentials for infection: (1) Lowered resistance due to the economic straits to which the family has been reduced; (2) the massive dose of infective material available and active—this latter the outcome of bad housing conditions. Neither of these factors is of and by itself responsible for the spread of the disease, but there is a vicious circle set up. How complete is the reversal of this picture at the colony. The man receives a wage which, together with the subsidy, enables him to obtain an ample food-supply for his wife and family. He is instructed how to deal with the infective agent—the sputum; he occupies a house in which there is some possibility of conforming to hygienic laws. The children enjoy the inestimable advantage of good playing fields instead of a dirty street.

Conclusion.

The reason for the advocacy of village settlements is two-fold: (1) The prolongation of the life of the consumptive without increasing the infectivity of the case (the probability is that the infectivity will be very much decreased, but proof of this is at the moment wanting); (2) the healthy rearing of the next generation and the production in its members of increased resistance against the disease. These objects obviously cannot be attained by the mere provision of workshops for consumptives near towns even if the labour be subsidised. Indeed, such a method would seem to put a premium on infection. It would serve no useful purpose; it would conduce neither to the arrest of the disease nor the prevention of the spread of infection. All the adverse conditions of the infected worker's home life would be ignored and subsidised labour of an infective nature, with all its dangers to the community, would be allowed to wander at will through out towns.

The village settlement would provide decent conditions for the families of consumptives, and, on the other hand, a hospital for the most advanced cases.

Of all the departments of the colony none is more successful from the humanitarian point of view, none more advantageous to the general community than the section set aside for those suffering from advanced tuberculous lung disease. The cry of those who condemned the admission of advanced cases to a colony is drowned, and for ever; the complete success of the measure is assured. The grisly idea of a "home for the dying" is relegated to the past. The "hope" of the consumptive is encouraged to the end, the encouragement taking the extremely practical form of allowing him to observe other consumptives in the various stages of convalescence. The chances of getting better are always before his mind. And the effect on the minds of those who are comparatively well is exactly the same as on our own. "The other fellow has it, not I," and in this may be summed up the whole psychology of the position. Not necessarily side by side, but under specially defined conditions, all stages of tuberculosis can be accommodated on the same estate. It is an enormous advantage that it should be so; it has simplified the machinery of running the various institutions which are now considered necessary for the treatment of the disease. Moreover, it has simplified to an equal extent the running of the industrial settlement.

Village settlements when formed will differ from each other in a thousand ways. The industries carried on cannot always be the same, and the types of inhabitants will differ in different areas. It is impossible to sketch any hard-and-fast plan. The only matter of importance is that the principles laid down should be grasped and followed; a newer and fuller opportunity will then be offered both to the consumptive and the community for a beneficial readjustment of their mutual relations.

CLEAN CUPS IN THE NAVY.

THE Admiralty is, we are glad to see, arranging that in future all glasses, cups, and tumblers used in naval canteens are to be disinfected in boiling water as soon as they have been drunk out of. This follows on the decision to secure disinfection afloat that we mentioned in our issue of Oct. 11th, 1919 (p. 672), and should materially reduce the incidence of sputum-borne infections in the naval service.

PUBLIC HEALTH IN BRITISH HONDURAS.

THE estimated mean population for the year 1918 was 43,368. The birth-rate was 41·252 and the mortality 49·368 per 1000 of the estimated population. The excess of deaths over births was 342. The number of illegitimate births was 702 out of a total of 1799, or 39·02 per cent. With most other places in the world the colony suffered in 1918 from a severe influenza epidemic. Great distress and suffering prevailed. Whole families, especially among the Indian villages, were practically wiped out. In many cases no nurses or doctors could be obtained to visit the sick. Splendid work was done by private individuals in assisting the Government to deal with the situation. The death of Dr. Winter was due in a measure to his self-sacrificing and unsparing efforts to attend to the sick after he himself was attacked by the disease. Vigorous steps to reduce the prevalence of hookworm, which, with malaria, saps the vitality of the people in tropical countries to such an alarming extent, especially among the Indians, were carried out by the medical department with favourable results. Rain fell on 186 days in the year in Belize and amounted to 64·66 inches. The daily average number of patients under treatment and care was: in the Belize Hospital, 46·03; in Corozal Hospital, 8·62; in Orange Walk Hospital, 5·81; in Stann Creek Hospital, 4·85; in Toledo Hospital, 6·73; in the Lunatic Asylum, Belize, 66·04; in the Poor House, Belize, 49·25.

LIBRARY

An Oration.

THE REV. JOHN WARD AND MEDICINE.

Being the Annual Oration of the Medical Society of London, delivered on May 10th, 1920,

By Sir D'ARCY POWER, K B E, F R C S Eng, F S A,
SURGEON AND LECTURER ON SURGERY ST BARTHOLOMEW'S HOSPITAL

Mr President and Gentlemen,—In a previous address[1] I gave some account of the Rev John Ward, A M, vicar of Stratford on Avon, whose commonplace books have long been amongst our treasured possessions

I propose to day to consider his medical knowledge—as he reveals himself to us—in somewhat greater detail Even in his early days, when he was a resident Master of Arts at Christ Church, Oxford, he had a strong bias towards "natural science," as we should now call it—a bias which was strengthened by the original work of Willis, Lower, Wren, Bathurst, Boyle, and Hooke, whose names are household words to the modern student of anatomy, physiology, chemistry, and physics

At the Restoration, when those who had become inured to the rule of the Commonwealth found themselves somewhat out of harmony with the Royalists, Ward, like many others, determined to leave Oxford, and, having a competence, debated for some time whether he should become a divine or a physician He visited London repeatedly in the year 1661–1662, and attended the lectures of Sir Charles Scarborough at the Barber Surgeons' Hall in Monkwell street, visited St Thomas's and St Bartholomew's Hospitals, and made inquiries about the cost of foreign medical degrees Botany[2] and chemistry as the foundations of medicine greatly interested him, but the call of the Church prevailed He bought himself the Vicarage of Stratford on Avon, and remained there till his death in 1681. The bodies of his parishioners—dead as well as living—and especially their urines, interested him much more than their spiritual state, and where one page of his diary is devoted to texts, sermons, and theology, there are 20 dealing with medical topics Like many medical students of the present day he loved a prescription, and he eagerly noted down the formulæ which he had heard or seen used by an eminent physician Willis was facile princeps in his estimation partly because Ward had known him at Oxford, partly because Willis was just acquiring a good practice and was called into consultation in the more serious cases which occurred amongst Ward's parishioners and neighbours

Ward himself was like Boyle and Pepys, versatile and curious, a type of mind not uncommon amongst men of his generation He wished to know all that could be known about everything he saw If he went to a goldbeater's shop he desired to know exactly the processes used and the weight and thickness of the products, the pursuit of the Philosopher's Stone interested him greatly, not because he had any belief in the transmutation of metals, but because it led to chemical processes and was in the nature of experimentation In this respect he was a true disciple of Boyle—the author of the Sceptical Chemist—for all things were put to the test of experiment "Don't think, try,' was the watchword of the Oxford School of Science long before it was adopted by John Hunter, and in this school Ward was educated Fortunately for us he had a bad memory and therefore committed his thoughts to paper, we are thus enabled to follow their train In the long winter evenings he read much, and it was his habit to make a digest or running commentary upon what he read Riverius, Fuller's Worthies of England, Velthusius, Willis's De Cerebri Anatome, Lower, Boyle in all his works, and Highmore were his constant companions, and throughout the period under consideration—1660 to 1668—he must have given a standing order to his bookseller in Oxford to send him, not only the new books on science as they appeared, but even the new editions He must, indeed, have been in possession of a very good library

There is no doubt that he prescribed for and treated his parishioners of the humbler ranks, although there was an apothecary and at least one physician living in Stratford during his incumbency He considered it a part of his parochial duty and the services he rendered were gratuitous Such treatment of the poor by the parson of the parish does not seem to have been unusual, for he says —

> 'Watson Parson of Sutton Coldfield in Staffordshire hath an extraordinarie way of cureing dropsies by ye help of pills and a dyet-drink Hee hath likewise a kind of Unguent made, as I suppose of Tarre and ye basting of a shoulder of mutton and of soot (as they tell mee) or some such thing and this cures any sore presently

This was clearly a crude form of Unguentum Picis

From time to time, too, he did a little minor surgery, and he has a good surgical aphorism "Allways lay a wound open whether it bee fresh or ulcerated" He says —

> 'Remember to get a speculum oris and other instruments fit for chirurgerie when I goe to London and a great case to hold them

There is a note —

> Issues made in children's necks att 2 days old good against convulsion fitts Remember to cut ym with my owne hand and frequently to let blood with my owne hand In making Issues use a green pea to draw, Ivie peas made of Gentian Roots peas made of Hermodactyl as I have heard 'Remember in Agues and ffeavors 1st to bleed and then to give my powder and plaisters to break ye neck of ye disease afterwards

He was observant of cases as they came under his notice and seems to have had some idea of the metastasis of cancer, for he writes —

> 'Persons yt haue Cancers after a while haue glandules arising in other parts wch may infect further although ye other should be taken out

Contemporary Methods of Treatment

The contemporary methods of treatment can be gathered from various entries Thus, of pleurisy with effusion, Ward writes.—

> "When an incision is to be made into ye Breast open itt betwixt ye 3rd and 4th true ribb reckoning upwards yt is just aboue ye diaphragm and to yt purpose apply a Caustick wch is very strong and will eat through ye Muscle yn make an Incision and keep itt open with Tents This course was taken with one who had an hydrops pectoris and itt evacuated much water but at last itt ulcerated and ye man died A Caustick if well made in two hours does ye buisnes 'That person yt had a hydrops pectoris with laying one hand uppon his breasts and another upon his back and shaking him ye water swashed so about yt those that were by heard it plainly

The treatment of lunatics was drastic

> "A good course for mad people (is) to bleed att both armes and att both feet and yn att ye haemorrhoids by Leeches yn att ye Veine of ye forehead and tongue and nose and att ye temporal artery Extract of Hellibor gr x once in 4 or 5 days very good for madness proceeding from melancholia Many mad persons not cured till 60 times bleeding

Hysteria seems to have been a common and troublesome condition then as now Dr Willis and Dr Highmore both wrote on the subject and Ward makes repeated reference to them The cause was none the less mysterious because it was supposed to bear a relation to "the rising of the mother," the deeply ingrained idea that the uterus was an animal with an independent existence and capable of independent movement in the body Ward says of the cause of hysteria—

> Enquire whether histerical fitts may not be caused by ye wombe rising uppon an object which is beloved and likewise from wind so ye erection of ye yard may proceed from a wind distending itt wch wee call a satyriasis Histerical fits are of several kinds some voluntarie as in (1) erect virg (2) some proceeding from wind (3) some from ye suffering of ye matrix either by emptying of a great Burden as after child bearing or by doing itt wrong in wounding itt in bringing forth ye child (4) or by fumes elevated remember to peruse Dr Highmore on this subject

Highmore, a friend of Harvey, is still known to us by the antrum of Highmore He wrote a small 12mo, published at Oxford in 1660, with the title "Exercitationes duae De Passione Hysterica" Ward evidently looked at the book, for on page 4 is "Sternutatio si superveniat cito paroxysmum claudit." and a few pages further on Ward asks himself—

> Whether itt is not very proper to cause histerical women to sneeze by putting up Orange pill [peel] into their noses or some other way

There was also—

> Aq Histeric and Cinnamomi for women in labour or neer fainting fits Whether fits of ye Mother are anything else besids a meer ventositie of ye wombe

---

[1] The Lancet, 1916 ii, 665

[2] The Annals of Medical History vol ii 1919 p 109

No 5046

The treatment differed with different practitioners; thus—

> "Dr. Trig cured a woman yt was troubled with historical fitts this way; he laid her uppon ye ground with her face downwards yn took up her coat and gaue her 3 or 4 good slaps on ye arse and they cured her, but I was informed yt he did this before much companie, which I scarcely believe."
>
> "Dr. Willis used with historical women this method;—1st. vomited ym; next gaue ym pills and cured several."

EPIDEMICS IN THE SEVENTEENTH CENTURY.

Small-pox, measles, and the plague appear to have been the chief epidemics from which the Stratford people suffered. Tubercle was rife as always; ague was endemic, as the Avon is liable to flood extensively and there are plenty of midges.

The new disease.—The following note was made in February, 1660:—

> "Dr. Eliot sayd hee did obserue yt in some persons who died in ye late new disease yt their faces were very red, their eyes much blood shot, whence hee concluded they would die but before death they would spit blood and pisse blood; and accordingly itt fell out."

Small-pox.—There were several outbreaks of small-pox at Stratford between 1660 and 1666, for the disease was always present before the age of vaccination. It was looked upon as a disease which occurred in the ordinary course of events, and many of the professional beauties of Charles's Court owed their reputation to the fact that they were not pock-marked. Ward notes in January, 1665–1666:—

> "Ye small-pox this year are less yn usuall as hath been observd by diverse: whence that may proceed?"

He writes almost directly afterwards:—

> "R Aq. Theriacal. with Syrupe of Gylliflowers to bee giuen in ye Smallpox when they first come out. The smalpox this yeer haue skaled and yn Risen down againe." "It is an ordinarie thing to haue convulsions goe before ye Eruption of ye smallpox as in Mr. Taylor's Sonne, Mr. Tent's Boy; Remember to obserue itt." "Vomiting a usual signe of ye smalpox, if itt precedes as in David att Mr. Jhonston's." "The Small Pox this year doe ordinairily Rise twice. Some new ones come out after ye others are allmost Ripe as in Mris Townsend; Mris Watts and Seuerall others; yet I haue not obserued any to die of them uppon whom they haue so Come out; whether Nature's disburthening ittself after that manner (Partibus vicibus) does not make itt more safe, whereas were ye eruptions all together itt might be more oppressive to Nature and consequently more daungerous."
>
> "In ye yeer 1664 ye smallpox raged very much att Stratford-uppon-Avon; some they came out twice uppon; others they neuer fully came out at all, only appeared a little and went in againe and left a kinde of scruf on ye face. I suppose ye alteration was accounted to ye masse of blood. I think they appear as soon in Whurtles uppon ye face as any where; especially on ye cheek." "I haue observd yt people that haue had ye smallpox are more difficult to sweat yn others, whether itt bee yt ye pores are straightened by ye pox so yt they cannot so well come forth. I mean such persons some 3 or 4 years or more after ye smalpox sweat not so kindly as others who neuer had them."

Chicken-pox.—The difficulty of diagnosing between small-pox and severe chicken-pox did not escape Ward, for he said:—

> "Obserue ye Chrystals what they are and how differing from ye smallpox and Measles and obserue somewhat about ye (origin (?)) of ye pox and other things about itt."

Measles.—It is somewhat remarkable that no thought of contagion entered into Ward's mind in connexion with small-pox and measles. The plague he knew was catching, but measles and small-pox he believed to be climatic or, at any rate, seasonal in origin.

> "The measils a general disease in 1661 yet not much mortal: yt yeer was a cool spring and an exceeding hot Summer." "I obserued one yeer in Stratford after a cold winter, a cool spring and a very hot summer children had ye measels extremely and men about July had Agues and feavors in abumdance." "The Children after ye measils were gone had violent griping pains and skreking in their gutts with starting and frightful fitts." "In ye measils a little before they came out children had strange fits, very frightful and like convulsions so in ye small-pox." "After ye measils some had great paines in their bellies with wormes coming from them." "After ye measils went in people were strangely disordered, some with coughs, some with headache, some with one thing, some with another as doubtles in those diseases much of ye matter is left behind."

Diphtheria (?)—He also gives a note of a case which seems to have been diphtheria, for he says:—

> "Whether ye woman, I think of Luddington, who had her tongue so swelled did not die of a Thrush or ye Aphthae, which are, whether in ye Roof of ye mouth and sometimes black ones, exceeding daungerous." "There were seuerall persons this last plague yt had itt in their throats, whereof many died yet some recouered."

The plague, 1665.

> "Some in ye plague had 3 or 4 sores all att one time uppon them in this last plague." "When ye sicknes was declining one might obserue persons in London streets halting and holding their arms very strangely wch persons they concluded to haue ye sores uppon them. Dr. Wharton said all people yt died in ye Contagion died of ye plague; yt hee opened one yt had no tokens nor sores, yet was full of tokens about ye Breasts. When ye Tokens only appear and not a Bubo itt is less infectious." "The Plague ordinarily begins with vomiting; There are in itt Buboes yt appear in ye Emunctories; Carbuncles wch come anywhere; ye Blanes wch are things like blisters; and ye tokens wch are spots of bright flaming red colour: inquire of Dr. Hodges."
>
> "In every Parish in London there are 2 watchers so yt what euer disease a man dies of these 2 must see and signifie ere ye partie bee buried. They are commonly two old women and they haue 4d. or 6d. for their paines; so an apothecarie in London told mee."
>
> "Towards August in ye yeer 1668, when we had a strange winter, a strange forward Spring and a strange moist summer, men had frequent swellings about ye throat; pains of ye teeth and such like distempers."

VALENTINE GREATRAKES, THE "STROKER."

Ward gives some interesting facts about Valentine Greatrakes, the celebrated "stroker," or, as we should now call him, the Christian Scientist. Born in Ireland in 1629, and living until 1683, he was in the height of his fame when Ward's entries are made—no doubt from personal observation—in 1666. The Lady Anne Conway, to whom reference is made, was a metaphysician, the wife of Edward Conway and the daughter of Sir Heneage Finch, Recorder of London and Speaker of the House of Commons. After her marriage in 1651 she lived at Ragley, still the seat of the Marquis of Hertford, whose second son bears the title of Baron Conway. Van Helmont, her physician, was in constant attendance, as she suffered continually from severe headache, later associated with fits. In spite of this affliction Lady Anne wrote much and was thought to be one of the most accomplished women of her generation. Greatrakes, who had cured a great number of people in Ireland gratuitously by stroking the part affected, was summoned to Ragley in January, 1666. He was unsuccessful in curing Lady Anne, but during his three weeks' stay he relieved so many persons in the neighbourhood that Dr. Stubbes, the physician at Stratford-on-Avon, published a 4to volume at Oxford in February, 1666, with the title "The Miraculous Conformist." A counterblast was issued by David Lloyd entitled "Wonders no Miracles."

When Greatrakes failed to cure Lady Anne Conway she went to Paris in the hope of being trephined, but the courage of the French surgeons failed them and she returned to England unrelieved. She died in 1679.

Ward's allusions to Greatrakes and Lady Anne Conway will be readily understood in the light of these facts. He says: "The Lady Conway hath great pain in her head, her sutures open." This entry suggests that she may have been suffering from the form of chronic hydrocephalus associated with closure of the foramen of Magendie. In such cases, as my friend Mr. L. B. Rawling reminds me, the intellectual faculties are often increased. If this were so, the French surgeons were perhaps to blame for not having operated.

> "Ye Lady Conway hath something like ye Irish ague. Shee is a great phylosopher. Henry Moore of Cambridge allmost perpetually with her in her chamber."

This was Henry Moore whose uncle threatened to thrash him before he went to Eton at the age of 14 "for his immature fondness in philosophising concerning the mysteries of necessity and free-will." He had a high opinion of Lady Anne Conway, whom he used to call his "heroine pupil."

Ward heard—

> "yt ye Ladie Conway is Sir Heneage ffinch, his eldest sister and a right ffinch—very proud. Yt she came into this miserie by a Brother of hers who had some skill in physick and Chymisterie and tried experiments uppon her; inquire whether itt was not ye same man yt travelled with Jeremy Clark." "My Lady Conway hath a tumour on one side and a scirrhus of ye Mesenterie as is supposed, as Mr. Stubbs says."

Ward had no high opinion of the veracity or methods of Dr. Stubbes, for he says:—

> "Inquire who yt is wch hath wrote a Book of Mr. Gretorixes his Cures wch is about as bigge againe as Mr. Stubbes on yt subject then peruse itt making to my own thoughts some censures uppon itt." "An issue made in ye side betwixt 2 Ribbs for a consumption by Mr. Stubbs, a conceipt sufficient. Some yt made issues under ye Axilla, as Mr. Stubbs said (if it bee not a loud lye) as also Dr. Bathurst's opinion of an issue yt itt givs a vent to nature as hee illustrated in a Barrell wch when it hath vent, and yt ye eating of an onion or any such thing is discernible in ye issue. Hee talked of an extreme ebullition of water in ye Breast wch may Cause a Cough—a loud lye—and moreouer yt hee hath tapt an hydropick person and there hath water come out of his bellie wch skalded ye hands—a loud one. His pretense of understanding ye distinction of feavours and of fluxes together with his rambling discourse of unusuall authors."

Ward had clearly formed an unfavourable impression of Dr. Stubbes, whose cloudiness of thought had probably led him to write the pamphlet, alluded to above, in favour of Greatrakes's cure The methods of treatment recommended for Lady Anne Conway are probably the instructions given by Dr. Willis :—

' First purge per ἐπίκρασιν; yn Bath her feet well, shave her head and apply to itt ye Lungues of sheep warme, new taken out of their bodie ' "My Lady Conway took much of his (Dr Willis s) ens Veneris and is much worse since ye taking of yt Hues his powder "

There are a few more references to Valentine Greatrakes, thus :—

"*The way to cure a deaf ear taken by a Barber at Thrapstone* — first syringe ye ear well yn drop in 3 drops of oil I suppose itt was sallet oil, into ye ear, doe this 3 or 4 times and ye end of doing itt is *to loosen ye matter wch stops ye ear, wch after by often* syringing comes out, sometimes a skinne, some times ear wax as bigge as one s finger end, ye oil is either common sallet-oil or *else some oiley infusion as appeard by ye smell I think* such a method safe and good praemising first purging and Mr Greatrakes his Method to break ye Aposteme by shaking *ye ear by putting ye finger* into itt besids thus loosing ye ear wax as I thinke Deafness is either natural or else itt is catcht by sweating or after a feavour keeping ye head too warme a great cause of *deafnes*, said Mr Gratrack, hence, said hee, there are 10 women deaf for one man and amongst women many countrie women for one Gentlewoman

This is evidence, I think, that the Irish used the shawl as a head covering and the Warwickshire women wore cotton bonnets as they still do.

' Mr Getorix in curing a deaf ear used to lay his ear to ye parties and then thrust his finger yn and so brak ye Aposteme, but ye end of laying his ear to itt seemd to bee this to hear ye swaging of ye Aposteme '

This, however, was a faulty deduction on Ward's part, for the Stroker used a certain amount of mystery, and used to whisper in the patient's ear, "God Almighty heal ye for His mercy's sake."

CERTAIN CASES DESCRIBED.

Ward gives sufficient details of the illnesses of some of his neighbours and parishioners to enable a diagnosis to be made, though in other cases the nature of the disease is puzzling.

Dilated stomach —*The following appears to be a case* of dilated stomach —

"My Lord of Down yt now lys at Roxall, euery night vomits after his first sleep and to yt purpose hath 2 chamberpots allways by him, one to pisse in and another to vomit in "

Enlarged prostate.—There is little doubt that the following was a case of enlarged prostate —

"Dr Gordon, Bishop of Exeter and lastly of Worcester died of a stoppage of the urine wch was supposed to bee ye stone, wch was by a probe often before opened but after being opened no stone appeared but only 2 peices of flesh growing one against another in ye neck of ye bladder yt ye urine could not passe This was strange yet true '

Hay fever.—The next case was one of hay fever.

"A strange sneezing wch Mr Cary of Nobal was troubled with, hee would sneeze 2 or 300 times together, but as soon as ye first frost came itt would leave him in ye winter, yn come againe in Summer with extreme Vehemency, afterwards hee fell into a quartan Ague and an intollerable head ache, with a vomiting allmost all he took, wch might be caused by a metastasis of ye sharp humour from one part of ye braine to some other part

I would suggest that his accessory sinuses became infected and that "the quartan ague" was evidence of suppuration.

Hydatids of lung (?)

' Mylward beyond ye Bridge (i e , Clopton Bridge at Stratford on Avon) brought mee ye bagge *of an Imposthume* wch came from her Daughter or Neece, ye thickest that euer I saw , ye wench felt it long under her left Breast and itt bled and trickled very warme, as shee thought, but about 9 days agoo ceased This morning shee was taken with a Reatching and att last up comes a quart of blood and after yt ye Bagge wch Mris Tyler caught hold of and brought up—very thick '

The question is whether itt comes from her Breast or not or whence itt should come It is probable a Vein was opened in her Breast by strayning herself to take up a payl and so ye mater collected and Imposthumated

If I had to guess about the nature of this case I should hazard that it was an hydatid cyst, "the quart of blood" being blood stained hydatid fluid, or else that the wench was hysterical and had *produced* a *pig's* bladder filled with blood

Other cases.

"A Wench, January 28 (1663-4) vomited up blood, her name was Myllen beyond ye Bridge, wee gaue her some opening pills, supposing it might bee her terms wch might flow yt waye

Another wench at Alderminster wch after heating herself and drinking sate downe to weed in ye Garden and was taken with such a paine in her joints yt shee *could not* stirre, *she was likewise much swelled* Shee was a very fat wench before '

"Make some obseruations of Mr ffrauncis Smith First his stomach grew weak and hee vomitted up all he took, yn came a hiccough and lastly death came suddenly

Clearly I think a case of intestinal obstruction due to carcinoma

' Goodie Cole was so sick yt euery one thought shee would haue *died and* wee gaue her —Lenativ , Cremor Tartari Resin Jalap and some juniper berries and itt brought away ye wind and she grew very well quickly after itt, and withal now and then took a graine *of laudanum* or 2

MIDWIFERY AND GYNÆCOLOGY.

One or two deaths after child birth are noted thus.—

"Itt is daungerous combing a woman s hair in a short time after her lying in as in my Lady Clopton s case wch was done a week after In my Lady Clopton s case they would give her no opium for fear of fixing ye Tumour, they blooded her in ye feet and behind ye ears with Leeches '

It would appear from this that the careful arrangement of the hair previous to lying in is not really for the comfort of the patient, as is usually thought, but is connected with a world wide superstition of the intimate relation of the exuviæ with the life of the individual.

'Mrs Higgins first was extreme hot and Restless before shee was delivred, afterwards her Courses broke downe ye child hid she was delivred with but in 2 or 3 days died After her delivry shee fell into a Cough and phlegme followed her much and about a Month after her deliverie her Legges swelled and yn shee died

In the course of his duties Ward saw much of his sick parishioners and the diseases of women and children especially interested him He was constantly trying to improve his knowledge and learn helpful methods thus :—

"Inquire more distinctly of Goodie Rickets concerning ye Lochia and ye Waters, how usualy they come and in what quantitie in or after deliuerie in child bed

"I haue heard of a woman yt had a procidentia uteri 9 or 12 yeers together, and yet did not gangrene but shee did well and meeting with some Balls put it up and itt staid and she had seuerall children after yt time ' "The Loosening of ye Ligaments or sometimes ye breaking of them is ye Cause of itts falling ' A pessary made in a procidentia uteri of cork with a hole in itt to let passe ye faeces uteri and so couered ouer with wax and some astringent powders mingled with ye wax and putt up ' Whether ye 3rd fitt in an ague or feavour is not more yn ordinarily daungerous as I experienct in a woman—Old Midwife Webb of Snytterfield

Ward occasionally made an effort to generalise from the particular—a faculty which was only just developing in connexion with medicine, for he says —

"Whether a great desire to liue wch some persons manifest uppon their sick beds, as allso a willingness to take any thing wch before they Refused is not a sign they are tending to their long home obserue itt more frequently than formerly

AGUE.

Ague was of frequent occurrence and there are numerous references to it, but it should be remembered that whilst there was much malaria the term ague was used for many cases of fever due to other causes.

"I aduisd one yt had a Quartane to drink Scurvy grasse drink and hee did so and found his well days were much better yn before he drank itt '

Ward learnt this treatment from Dr. Bates—Oliver Cromwell's physician—who practised first at Oxford and afterwards in London, and was known as the "Scurvy grass doctor."

"Allways take a surfeit or an Ague with a vomit in ye beginning If pain in ye side bleed to bee sure What if a man should giue 3 *or 4 drops of* spirit of hartshorne or spirit of salt or any other volatile spirit constantly in a quartan ague to exalt ye blood by degrees, and so to get ridd of itt sooner A surfeit or aguish feavour *coming* after a quartane, ye body not being duly purgd after ye Quartan usualy ends in death, obserued in Mris Hopper of Loxly and Rowly of Eddington attempt such people with a vomit *first in cas* I bee calld bleeding does little '

In connexion with ague he gives an older variant of our adage, "Stuff a cold and starve a fever," for he says "Starve an ague and stuffe a cold "

DISEASES OF THE GENITO URINARY ORGANS.

Diseases of the genito urinary organs interested Ward nearly as much as the diseases of women and children, and a queer contemporary treatment is thus recorded :—

"A Bath usd by Mr Canon of Bampton by advise of a Dr when his water had been stopt 9 days *when hee* first went in to this Bath hee felt easd ye 2nd time hee beganne to faint but lying downe in his bed hee recouerd and yn pist with such violence yt ye stones might bee heard Rapping *against* ye pott side Mr Canon of Church Bampton was often sett uppon his head by his sonne in lawe and then throwne downe to trie if possible to shake ye stone out of ye neck of ye *bladder* but all would not doe

Ward does not say whether he had any twinges of the stone himself, but the mention of the bath in the case of Mr. Canon is followed immediately by the entry :—

"Gett a furnace to heat water in for a Bath and a Cock to lett itt into ye Bathing Tubb, when hott ' *For ye stranguric Brew*

> some new Beer every morning for 12 mornings together and drink a quart of yt ye first (thing) Barme itt but doe not hopp itt; itt must bee fresh brewd every morning."

Another parishioner died of suppression of urine for—

> "John Ventries told mee yt whilst his wife was sick no urine came from her in 11 or 13 dayes but her hands smelt of urine and all her bodie; yea, ye Curtains yt hang about ye Bed and ye hangings of ye Roome; yea, he said that when shee died she had nothing in her bladder notwithstanding shee was so long without urine. Whither should ye urine passe but per halitum."

Urinoscopy.

In his own opinion and probably in that of his neighbours as well, Ward was very skilful in urinoscopy, and there are many entries on the subject.

> "Remember still to prognosticate by women's urine pains in their back." "A woman who had miscarried 3 weeks before sent her water to me. I obserud in itt much white flying consistencies wch very quickly settled to ye bottome in a white substance: itt argued some distemper of ye womb: for itt somewhat resembled ye sediment of childing women." "Mr. Lingen's sonnes water was palish like yt of strangurian persons and had much setlement in itt: hee had an intollerable paine in his head wch was I suppose a Collection of water gathered there after a feavour, being neuer purged." "Whether ye black urine does not allways signifie ye stone or ye black Jaundice." "In feavours when ye water is first high, yn muddy itt is a good signe, but if itt continues high not so." "When ye water is white remember in judging urines to harp uppon these things: ye wormes, paines or flux in ye bellie and paines in ye head." "There is great diversitie of urines: but yt of children and such as drink Rhenish is ye best."

Venereal Disease.

Syphilis and gonorrhœa were rife at Stratford-on-Avon during Ward's incumbency. He distinguishes clearly between them, but neither disease incurred his moral disapprobation. He looks upon them in a purely scientific spirit and as diseases to be cured. Of prophylaxis he says:

> "The way to prevent ye pox is by syringing as ye Duke of Buckingham and some other madde fellows doe, or else by taking a horse and riding immediately after wch I haue heard is ye most undoubted way." "Mich. Palmer troubled with a gonorrhœa and a swelling in his groin wch swelling seemd to mee who handled itt to bee about ye upper part of vasa deferentia towards ye bladder, itt is much swelled sometimes. Whether itt may not be caused by *ye putrefying of some humours about ye part or rather ye sperme.*"

This appears to have been a case of gonococcal infection complicated with a hydrocele, but the term gonorrhœa was used in its etymological sense. It consequently included the discharge in cystitis, tuberculous disease of the kidney, prostatic abscess, as well as the specific inflammation due to the gonococcus.

ON EMBALMING.

Even death did not end the interest he took in the bodies of his parishioners. He gives details of the process of embalming, and it would not surprise me if an embalmed body were found some day in the churchyards of Stratford or Welford, the two parishes which he served.

Malignant Disease.

> "In the Autumn of 1665 a cancer in Mris. Townsend's Breast of lveston was taken off by 2 surgeons. First they cutt ye skinne s and laid itt back; yn they workt their hands in ytt one above the other below and so till their hands mett and so brought it They had their needles and waxt threads ready but never them, and allso their cauterising irons, but they used them Shee lost not above ℥vi of blood in all. Dr. Needham ...... itt was a Meliceris and not a perfect cancer, but it would have n one quickly. There came out a flow of a great quantity of erish substance as much as would fill a flaggon. When they d done they cutt off one one bitt and another another. Put a lass of wine in and some lint and so let it alone till next day. Yn they opened itt again and injected Myrrhe, Aloes, and such things as resiste putrefaction and so bound itt up again. Every time they dressed itt they cut off something of ye cancer yt was left behind. Ye chirurgions were for applying caustick, but Dr. Needham said 'No, not till ye last, since she could endure ye knife.' They prepared her body somewhat, yn let her blood ye day before. She endured it with infinite patience all along, not offering to lay her hand uppon itt to ease itt, but a warme cloth to ye other breast all ye time. ...... The way how and where itt should be cutt away was markt out with Ink by one Dr. Edwards, who lives at Bridgnorth. ...... Hee said iff they could prevent a Gangræna there was little fear, butt itt might be a cure iff she fell not into a feavour."

She recovered from the operation, survived an attack of small-pox, and died a year or two later. Ward records the post mortem.

> "Mris. Townsend of Alveston being dead of Cancer Mr. Edis and I opened her breast in ye outward part and found itt very cancrous; itt had been broken and a Mellicerous part was yet remaining when wee saw itt; wch being Launct yeilded 2 poringers full or more of a very yellow substance wch came plentifully out of the Cauitie of ye breast; yt flesh wch was grown againe after part was taken out was of a hard, grisly substance wch seemd very strong. The Ribbs were not putrified as wee could discouer nor anything within ye breast of a Cancrous nature for wee runne ye knife within side ye breast through ye intercostal muscles. Dr. Needham hath affirmed yt a cancer is as much within as without ye breast and hee hath seen a string, as I was told, going from ye breast to ye womb. I suppose itt was ye mammillarie veins full of knots wch were cancerous and hung much like ropes of onions. The cancer was a strong one as was evident; wee wanted spunges and things conuenient or else wee had opend ye cauities of ye breast."

REFERENCES TO CONTEMPORARY PHYSICIANS.

Ward says of physicians generally—

> "There are seueral sorts of physicians 1st. some yt canne talke but doe nothing; 2ly some yt canne doe but not talke; 3rdly some yt canne both doe and talk; 4thly some yt canne neither doe nor talk and these get most money."

This was merely a jest, however, for some of the men he most revered were his friends and contemporaries, the great physicians of their age.

Perhaps the most interesting observations in Ward's note-books are his references to Dr. Willis, Dr. Lower, Robert Boyle, and others of his contemporaries who were personally known to him as graduates of Oxford. The references to the Hon. Robert Boyle, the chemist and physicist, are so numerous that they cannot be dealt with at present.

Dr. Thomas Willis.

Dr. Willis, described by Needham "as next to Dr. Harvey, the glory of our English nation," gave his name to the circle of Willis, and is now remembered as an anatomist. Ward, however, knew him as a practising physician, and throws much light upon this little known side of his life. Willis left Oxford in 1666 and settled in London, taking a house in St. Martin's Lane, where he soon obtained a large practice, not wholly to the liking of the other London physicians, for Ward says:—

> "Sydenham and some others in London say of Dr. Willis yt hee is an injenious man but not a good phisitian and yt hee does not understand ye way of practice."

Be this as it may, Willis drew attention to wasting disease associated with sweetness of the urine, and may thus be claimed as the discoverer of diabetes mellitus. He also wrote on hysteria, and Ward says:—

> "Dr. Willis used with histerical women this method 1st. vomited ym; next gaue pills and cured seueral."

Ward records:—

> "Crabbs eyes powdered and put into vinegar where they will ferment, yn decant ye vinegar and after yt make use of itt. Dr. Willis his receipt. Remember yt I inquire of D. C."

D. C. was Court, who was "prentice to one Mr. De Laune an apothecarie in blackffryers in London." Mr. De Laune is now known to us as one of the early masters of the Society of Apothecaries.

> "Remember to inquire about Dr. Willis his syrup of sulphur when I goe to Oxford and see and buy some of itt." "Whether a disturbed urine does not usualy signifie some paines in ye head. Remember to trie itt." "Whether ye giving a clyster euery day to persons in a malignant feavour with salt of wormwood and a spoonful of juice of Oranges is not very proper. Dr. Willis usd itt with Mr. Levine." "Dr. Willis after his antiscorbutick electuarie made of cons. of Lujula, Cochlearia, Crabs eyes and spec. Diatria. santalon and juice of Lemon with troches of Rhabarb." "Prescribe juice of nasturtium, dandelion and juice of scurvy grass with white wine to take six spoonfuls of itt after ye electuarie. Dr. Willis hath an admirable way of making juleps but not by distilled water as many doe." "Remember to trie sulphur and honie for a cough and garlick pricked ful of holes and butter. Dr. Willis his balsame of sulphur some such thing." "Remember yt I inquire what Dr. Willis his dyet drink was and resolue to make much use of dyet Drinks in Hectiques and know like wise what Sallamans dyet drinke is and means." "Dr. Willis praescribed Vervaine water and ye powder of Vervaine for ye headache." "Salt of Tartar and Ginger ye best way of praeparing Apium withal, as Dr. Willis affirmes."

Parsley was used in coughs and colds as well as a lithontryptic. The use of salt of tartar is an indication of Dr. Willis's adherence to the newer school of chemical physic as opposed to the older physicians who depended rather on herbs and roots for their remedies.

> "Dr. Willis advised Mr. Treble to infuse filings of Iron in white wine yn mix with itt aq. Limacum composita and aq. Lumbricorum. When hee took ye water hee took pills constantly and an electuarie."

The iron tonic here recommended would probably have been equally satisfactory without the snails and earthworms, though there are some who still believe in the virtues of mucin.

> "Dr. Willis much commends Firres ale; I suppose because it holds sulphur in itt wch volatilises ye blood." "My Lrd. of Downe dead under Dr. Willis his hand in fluxing as I hear." "Dr. Willis hath rich peaces of plate presented him as well as great ffees as Mr. ffrancis says." "Dr. Willis his purges generaly are very gentle ones but on ye contrarie Dr. Speed's are very feirce." "Dr. Willis said yt ye Duke of Cambridge had mala vitæ stamina."

This was equivalent to saying, in the language of the present day, that he had "specific disease." It was spoken of Charles, Duke of Cambridge, who died on May 5th, 1661, the eldest child of James II —then Duke of York—and Anne Hyde, his wife The statement is said to have cost Willis the Court practice which he was just acquiring, though, as Willis was a staunch Protestant, there may have been other causes to account for the loss The child afterwards came under the care of Sydenham, for Ward says —

> There was a great phlogosis in ye Duke of Cambridge his bowels Dr Sydenham kept ye Duke of Cambridge alive 3 weeks and the Dutchess thought hee would really have cured him hee did itt by some cooling water or other wch hath got him some credit Hee was also with Sir Richard Bishop for his gout but did little except pultisse him with milk and crumbs of bread Hee aduised Mr Bishop to fast one day in a week for his Rheumatismus so yt humor would spend ittself

Salt of vitriol is reckoned by Dr Willis amongst such vomits as work gently

> ' Remember yt I studie ye Braine more particularly with its office and use and diseases incident to itt according to ye new anatomie and not ye old stuffe (1663 October)

In pursuance of this design Ward must have bought Willis's Cerebri Anatome as soon as it was published, for in February or March, 1664 65, he makes extracts therefrom

Blood Transfusion by Dr Lower

There are various entries about Lower, and descriptions of experiments conducted by Lower or at his instigation

> A dissection Thursday November ye 16 (1664) first of ye Testicles of ye spleen then of a bitch wherein wee saw many excellent things ye parastate vasa deferentia prostate and so ye common passages Syringe some ink into ye Crural arteries and itt appears in ye vein wch argues an anastomosis

It is clear from this that the anatomical proof of the circulation was not yet complete

> Dr Lower let one dog s blood into ye bodie of another by opening ye veins of one and ye arteries of another and putting in a quill into each and so letting one blood on ye other side ye one died ye other liud another dog yt had 2 Vena Cavas as they say —Dr Lower
>
> They had syringed in Beer into ye Crurall Arteries and likewise Infusi Croci Metallorum

The crocus metallorum, or liver of antimony, was a violent cathartic and emetic It was given in doses of from 3 to 6 gr.

> After a dogge hath been let blood and lies dead at your feet you may let ye blood of another dogge into his veins and so reuiue him againe inquire further into ye truth of it

These experiments of transfusion are recorded by Ward in the year 1665 They refer to Lower s classical experiments on transfusion which were suggested by Christopher Wren s injection of various drugs and poisons into the veins Lower passed blood direct from the artery of one dog into another in February, 1665, at Oxford, in the presence of Robert Boyle and others Ward perhaps rode over to Oxford from Stratford to see the experiment On Nov 23rd, 1667, Lower transfused Arthur Coge at a meeting of the Royal Society, but it is only in the recent war that his methods have been employed so extensively as to have passed beyond the experimental stage They are now firmly established as a remedial measure of great value in properly selected cases and with some modification of technique

> The Diaphragma is a muscle and is of use in Respiration and I haue heard yt Dr Lower says yt broken windedness proceeds from a breaking some vessel in ye diaphragme and yt hee can make a dog suffer and appear as broken winded by cutting them
>
> Linseed oil and oil of sweet almonds usd by Dr Lower to bee likt with a stick of Liquorish for distempers of ye lungues Dick Lower told mee yt they had searchd ye Testicles of a Boar and could by no manner of means find yr any but one small nerve coming thither whence they conclude yt ye sperme cannot be ye result of ye succus nervosus but somewhat else from ye arteries

This was a part of the experimental inquiry which destroyed the long established hypothesis that the fructifying power of the semen was derived from the nervous system in the form of a succus nervosus

Sydenham, Scarborough, and Prujean

> Dr Sydenham aduises a vomit 2 hours after a gentle dinner after vomiting hee giues a narcotick potion or Bolus to allay ye tumult yt ye vomit hath made

Of Sir Charles Scarborough, to whom Dr Harvey left his gown, Ward says —

> Dr Scarborough There was a person dissected att London about October 1664 who wanted the pectoral muscles yet had ye right use of his armes as I heard wch Dr Scarborough said was neuer heard of before

Sir Francis Prujean

> "Dr Prujean came from Lincoln to London hee was a mean man at first and was faint to leave London twice or thrice because he could not get a maintenance there

Many of us, no doubt, have felt the same Sir Francis Prujean (1593 1666) was the son of the Rector of Boothby in Lincolnshire He was a sizar of Caius College, Cambridge, and after graduating he practised in Lincolnshire till 1638 He then settled in London and acquired a large practice, attending Queen Catherine when she had typhus fever, and became President of the Royal College of Physicians

Fraizer, Needham, Peachy, and Hollier

> The Queen s distemper I hear is too eager flowing of ye menses and thereof she is aduised to go to Tunbridge waters wch Dr Phrasier says will confirm and strengthen ye parts The King hath a high opinion of Dr ffrasier and says all ye physicians are fools to him A whey of Dr Phrasier for Mr Bishop ℞ Marmor Calabr ʒiij Cremor tartari ʒss Seri lactis lib ij Dr Phrasier gaue some pills to Mr Bishop for his Rheumatismus likewise but I imagine not with much success as appeared by ye effects

Sir Alexander Fraizer was a member of the Durris family and was born about 1610 He probably received his early education at Aberdeen and in 1635 he graduated M D at the University of Montpellier Returning to London he was elected a Fellow of the Royal College of Physicians in 1641 He was an ardent Royalist and shared the exile of King Charles II, who appointed him physician in ordinary after the Restoration, and created him a baronet of Nova Scotia in 1673 He attended many members of the Royal family and was in charge of the operation of trepanning Prince Rupert s head in February, 1666 He died in May, 1681 Clarendon says of him "He is good at his business, otherwise the maddest fool alive ' Fraizer had such influence with the King that once when he was arrested for debt he caused the bailiffs to be apprehended, committed to the porter s lodge and there, by the King s command, soundly whipped, from which the Justice himself very narrowly escaped

Dr Needham

> Needham allways aduises to praescribe even in feavours something against ye wormes hee hath proued itt successful Mr Needham a physitian livs sometimes in Shrewsbury sometimes out att Gentlemen s houses Needham saies there is use of old Commentators as there is old posts and stones though itt bee but to show where ye old Road was Says Needham I resolue only *there bee very great urgence or an immediate necessitie for sauing* life yt I will not open a vein Hee adds likewise unles there bee some other extraordinarie occasion for Physitians make blood letting but as a prologue to ye play

Marchmont Needham (1620 1670) was the son of an Oxford graduate who married the daughter of mine host of the George Inn at Burford Marchmont was a chorister of All Souls at Oxford and got his degree in 1637 Ward says at this period of his career he lived in the house of Dr Bathurst, with whom Harvey used to work at Trinity College Needham afterwards became an usher of Merchant Taylors School and was admitted a member of Gray s Inn in 1652 He was essentially a pamphleteer, writing both on the Parliamentary and the Royalist sides In 1665 he published the Medela Medicinæ which is here quoted by Ward It created a considerable stir in the medical world and was answered by Sprackling and Castle

Mr Peachy

> One Mr Peachy of London cures quartan agues hee first purges yn giues his haust 3 days when ye ague is to come itt sweats somewhat and they must keep their beds itt comes away by urine as hee says Hee acknowledges Gentian roots and ye Jesuits bark *in his haust*

If this is either of the two Peacheys of whom an account is given by Mr G C Peachey in *Janus* 1918, pp 121-158, it must, Mr Peachey thinks be John Peachi, Minister of S Paul s, Walden, who afterwards became M D Caen, and an extra Licentiate of the College of Physicians of London

Mr Hollier

> Mr Holliard ye great Chirurgion in Warwick Lane was a poor boy in Couenterie his father was a collier or at best but a poor shoe maker in Couenterie and one Dr Mathias (I think he was Queen Annes Dr) about yt time frequently coming to Combe Abby and using Couenterie much spoke to Abraham Ashby an Apothecarie there to help him to a boy to dress his horses and ride along with him, and Mr Ashby spoke to Mr White ye school master who told him hee could help him to one but his father was a foxing drunken fellow and ye boy yt hee helpt him to was this Mr Holliard ye Chyrurgeon afterwards Dr Mathias died and Mr Holliard got himself a little monie and put himself prentice to Mr Mullins his *father of* Shooe Lane and now hee comes to what hee is Dr Phipps likewise livd with this Dr Mathias before Phipps went to travel

This gossip about Hollier is interesting, and was evidently the contemporary belief. Hollier was the surgeon who cut Pepys for stone. He became Master of the Barber Surgeons' Company in 1673. I have given an account of him in "Occasional Papers of the Samuel Pepys Club," Vol. I., p. 58.

James Molines, to whom Ward says Hollier apprenticed himself, was "surgeon for the stone," and was reputed the most skilful lithotomist of his generation. He died in 1639, and he was succeeded both at St. Bartholomew's and St. Thomas's Hospitals by his son, Edward Mullins, a turbulent and quarrelsome person. Edward Mullins was accordingly dismissed from his post at St. Thomas's Hospital in 1664, his place being taken by Thomas Hollier. Edward Mullins, however, was reinstated as fourth surgeon to St. Thomas's Hospital in December, 1660, and died in 1663. Ward adds a few more details of Hollier, for he says:—

> "Mr. Charles Danvers married to ye daughter of one Mr. Holliard, a chyrurgeon, in London. Remember to write to him for a pair of gloues speedily." "Remember to write to Charles Danvers and to get intimate acquaintance with his father Holliard and to see Amputation made and Cutting of ye stone." "Inquire what ye vomit was wch Mr Brooks says Holliard gaue him wch was but a spoonful mixt with some other stuff wch made him vomit half a dozen times."

OBSERVATIONS ON DRUGS.

The properties of opium, laudanum, and antimony were the subject of considerable inquiry in Ward's time, and he makes several allusions to these drugs.

Opium and Laudanum.

> "The praeparation of Opium in ye Shops is Imperfectly done by adding saffron, cinnamon, and other aromatical druggs to make itt into a Laudanum, whereas ye correction is better performed by a digestion of opium in wine yt is impregnated with an equal weight of Salt of Tartar, ye great power of wch Salt is to correct ye violent as wel as ye Narcotick part of ye Medicine as may bee seene in Mathews his pill, wherein there is a great quantitie of white hellibore, and Salt of Tartar is ye great Corrector."
>
> "Laudanum dissolud in a little Treacle-water and a little syrupe added to itt is excellent in some cases—a graine and a half or thereabouts." "After ye taking of Laudanum, I obserud yt they rise againe very sick and hott and their sleep was only a slumber."
>
> "Starkey told me that ye sleeping properties of Opium may bee separated so as to make itt a hinderer of sleep but ye sudorific and anodyne qualities cannot."

Laudanum, therefore, was at this time a solid, and was dispensed by the grain.

Antimony.—The composition and properties of antimony were still the subject of much inquiry, because, under the influence of Basil Valentine's teaching, it was looked upon as a universal panacea. In 1678—12 years after Ward's notes were made—there were no less than 106 preparations of the metal in more or less common use. Crude antimony was thought to be a mineral consisting of (1) a sulphur partly golden and partly combustible; (2) an undigested mercury of the nature of lead; (3) of a saline and earthy substance. Ward writes that—

> ntimonie hath much salt in itt but little metallic sulphur only arsenical sulphur." "An antimonial (cuppe) is made of ye fashion of a horne." "Antimonie is a rare bodie betwixt and Lead, somewhat higher yn sulphur but lower yn Lead. rtley greatly aims att ye Mercury of itt, wch I belieue hee would open ye bodie of gold: and his reason is this because how itt mixes with gold and merges itt as in ye Antimonial. n allreadie separate ye good Sulphur from Antimonie and itt him in great hopes yt hee shall doe ye Antimonie only; hee there is an Arsenicall sulphur wch yet hee cannot get out and hinders his separation of ye Mercurie." "Antimonie melted gold wll make ye gold look just like itself if itt bee put in just when it is melted, but yn melt ye gold uppon ye Test againe and yt contrariwise flies away, itt purges and makes brittle ye gold yt is very certain." "Take ye emetike qualitie from Antimonie and ye Narcotick from opium and what canne they not doe."

CONCLUSION.

These extracts show the Rev. John Ward as a man of great versatility at a time when the prevailing type of mind was versatile. In many respects he was a true disciple of the Honourable Robert Boyle. Interested in medicine he would have made a good practitioner; a friend of Lower, as a physiologist he would have advanced the science. Willis could have utilised him, and had he stayed a little longer at Oxford he might have come under the spell of John Mayow, the most gifted of the band. Boyle had interested him in the new chemistry, and his restless curiosity led him into metallurgy and the more dangerous quest of the philosopher's stone. But with all this he was a dilettante—spoilt, I think, by the possession of a competency, hampered perhaps by ill-health. He was certainly ruptured, and he died the early age of 52, probably of phthisis.

THE APPLICATION OF BONE-GRAFTING IN THE TREATMENT OF FRACTURES.[1]

BY ERNEST W. HEY GROVES, M.S., F.R.C.S. ENG.,
SURGICAL DIRECTOR OF PENSIONS HOSPITAL, BATH.

UNTIL recent years bone-grafting has been an expedient used only in exceptional cases. But lately, owing to the work of Albee in America, and also to the large number of cases where a serious loss of substance in the shaft of a long bone has to be made good, the application of bone-grafts for the repair of fractures has become comparatively common. In fact, bone-grafting has been so much in vogue that there has been a tendency for zeal to outrun discretion, and so many failures and disappointments have resulted that it is liable to fall into discredit. When used properly, with due regard to vital and mechanical principles, it not only gives good results, but results which cannot be obtained by any other method.

The proposal that recent simple fractures should be treated by a sliding bone-graft taken from the broken shaft is unlikely to be widely adopted for good reasons. It is an operation requiring special skill and experience, and appears to do either too much or too little. In the great majority of recent simple fractures correctly applied axial traction, followed by early movements of the joints, will give rapid functional recovery which leaves nothing to be desired. For such cases bone-grafting does too much. In other cases where there is a persistent tendency to displacement of the fragments (for example, in the middle of the shaft of the radius or at the upper end of the femur) the little slender graft is not strong enough to maintain the osteo-synthesis, and the limb has to be immobilised for a long time in plaster.

Intra-medullary Bone Pegs.

Those recent fractures which require operative treatment usually present a displacement, which is caused or kept up by muscular tension or static conditions. The treatment required will thus be correct apposition and alignment, with as little interference as possible with the vascular and osteogenetic sheath of the bone fragments. Such a method of treatment is found in the application of an intra-medullary bone peg—a method which I venture to think is not sufficiently known or applied. The operation finds its simplest and most typical scope in the treatment of a fracture of the radius, where both ends are displaced towards the ulna, a condition which is almost certain to lead to synostosis unless this displacement is corrected. The pegs, which are 1 to 2 inches long, are made in sets of 8, varying in thickness from $\frac{3}{16}$ up to $\frac{1}{2}$ inch. Each has a small boss or ring at its centre, by which it is prevented from being pushed too far into one fragment. Three conditions limit the scope of the use of the simple intra-medullary peg: (1) the case must be a clean one; (2) there must be no comminution of the fragments; and (3) the fracture should be nearly transverse. (Figs. 1, 2, 3.) If used for the femur the short intra-medullary peg will not serve to maintain correct alignment and bowing will inevitably occur unless a suitable moulded splint or a walking calliper is used.

The bone-peg constitutes the simplest and most efficient type of bone-grafting for fractures that can be devised. The peg becomes rapidly permeated by living tissues and is incorporated by them in a period varying from 3 to 18 months. The bone-graft may have a double function to perform. First, it has to act as a mechanical strut or splint, and for this it requires strength and accurate fitting; secondly, it may have to take the place of lost bone; if no bone has been lost the graft will become absorbed. It is a consideration of these facts which should determine the choice between a dead beef bone or living autogenous grafts. If the graft has merely to act as a temporary nail or peg then the advantage is with the dead bone, because this can be chosen beforehand of the exact size and shape required, and, moreover, it can be taken of much greater density than is often possible with autogenous grafts If a graft has to be completely buried in vascular living bone, then a dead beef bone is just as efficient as an autogenous graft But it is quite another matter if it has to span a gap, for that part of the graft which is not in contact with living bone will survive only with difficulty, it cannot be converted into, or replaced by, living bone except by the very slow process of vascularisation from the two ends, where it is in touch with live bone If sepsis is present a dead bone graft will be capable of no resistance, but will be a focus for bacterial lodgment, but, as I shall presently show, living bone grafts are capable of some degree of survival under a moderate degree of sepsis, and although ultimately a sequestrum may be lost, yet a sheath of new bone is laid down which is probably derived in large measure from the cells of the graft itself

---

[1] A lecture delivered at the West London Post-Graduate College on Feb. 13th, 1920.

FIG 1

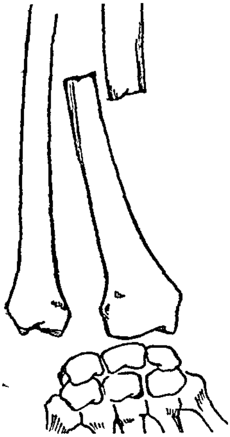

FIG 2

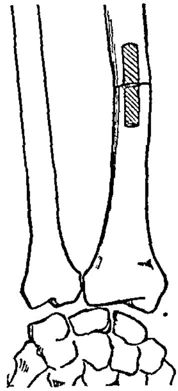

FIG 3

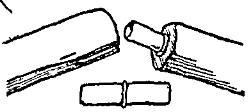

FIG 1 —Typical displacement of a fracture in the middle of the radius
FIG 2 —Short bone peg in position
FIG 3 —Showing how the short bone peg is inserted

I am much indebted to Miss D Pillers for the drawings used in illustration of this article

Exceptional circumstances sometimes justify the employment of beef bone grafts even for gap fractures One patient had already had an unsuccessful grafting operation done, the graft having been taken from his own leg. As he said that his arm was none the better and his leg was the worse for the operation, he naturally refused to have a similar operation repeated, but was prepared for anything which did not sacrifice his own tissues In such a case the graft is prepared from an ox shin bone of the exact size and shape required It is perforated by many holes, which facilitate its rapid vascularisation by the tissues in which it is laid

The Behaviour of Living Autogenous Grafts

I do not propose to enter into any discussion of the exact parts played by the cells of the graft and those of the bed into which it is laid Neither shall I attempt to determine the relative importance of different parts of the graft But I would like to point out certain easily demonstrated characters of the graft which have important bearings on the practice of bone grafting

1 *Limited power of growth* —A living graft does not grow at all in length, and only very slowly in thickness It does not become thicker unless or until it has become incorporated in the skeleton when it is subjected to the strains and stresses normally borne by the long bones From this it follows that the graft should, if possible, be made of the full length and thickness of the bone which it has to replace An illustration will make this clear A small piece of tibia has been inserted into a gap fracture of the radius After some months the graft had become rarefied and no union had occurred It was then sought to make the grafted bone firm by the addition of a plate, which was attached with difficulty owing to the fragile nature of the bone This had to be removed later because of the irritation caused by the plate just beneath the skin, and the fracture still remained ununited In this condition the patient came to me and I inserted a tibial graft of the same thickness of the shaft of the radius This has grown firmly in place, and now, six months later, forms an integral portion of the skeleton, as seen by X rays

2 *The importance of correcting deformity before the graft is inserted* —A graft cannot be expected to act as an intelligent agent and actively correct a deformity Obviously the deformity must first be corrected as far as possible, and then the graft of suitable size and strength must be so soundly fixed as to prevent recurrence of the displacement For example, in the familiar displacement associated with a gap fracture of the lower part of the shaft of the radius, the deviation of the radial fragments towards the ulna, with the resulting dislocation of the hand, it is necessary forcibly to separate the radial fragments from the ulna and to make the graft rather longer than the gap it has to fill, in order that the radius may remain bent outwards away from its companion bone The restoration of the radial curve is necessary to restore its "bucket handle" action, required for the movements of pronation and supination

3 *The necessity for firm fixation of the graft* —Whatever vital properties a graft may have it can only grow to its bony bed if it is fixed firmly thereto It is not like a vegetable seed or plant cutting which is capable of throwing out roots far and near, all it can do is to receive and contribute towards, a little cement substance which will join it to an adjacent live bone with which it is in firm contact Therefore wide apposition, accurate fitting, and firm fixation are essential to the vital union of a graft with its bed

Two experiments on cats' tibiæ illustrate this point In both half the thickness of the tibia was cut out for ¾ inch and the remaining shaft was divided In one the removed portion was replaced and tied with catgut in the other it was fixed by split pins and washers In both the leg was immobilised by a double transfixion apparatus In that specimen fixed by catgut the graft has become displaced and there has resulted a typical ununited fracture In the other, where the graft was fixed by metal pins, firm union has taken place

There is a modern tendency to credit metal sutures with a capacity for hindering repair Of course they may do so under certain circumstances, but, on the other hand, if they afford the best means of fixation of the graft to its bed they are of great value, even if they have to be removed ultimately Fig 4 is from a case of a gap fracture of the radius treated by a "cricket bail" graft in which the fragments of the radius were so fragile that it was necessary to bind them with wire sutures to prevent splitting The figure is taken a year later, and shows complete fusion between the graft and its bed, the wire still remaining in position It is perfectly true in bone grafting as in joinery that the best work consists in fitting without the use of nails, screws, or wire But there should be no hesitation in deciding that when fixation requires a metal suture this should be employed in preference to allowing a loose contact between the graft and its bed

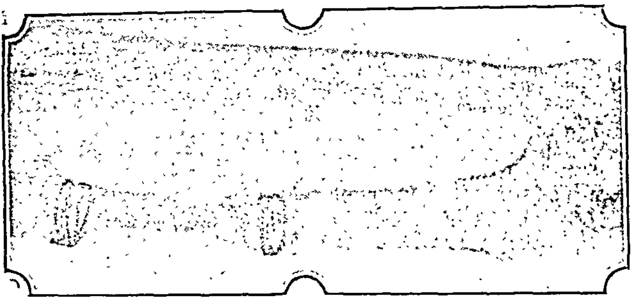
4 *The capacity of a living graft to survive under septic conditions* —One of the most striking qualities which distinguishes a living autogenous graft from a beef bone graft is its capacity for survival, in whole or in part, in septic conditions Two illustrations of this are given, but the phenomenon is of such common occurrence that these might be multiplied many times In the first (Figs 5 and 6) a gap fracture of the radius was repaired by two tibial grafts bolted together over the ends of the radial fragments After a few weeks a sinus appeared, and three months later the X ray showed a quantity of new bone round the periphery of the grafts and a central sequestrum in the middle The bolts and the sequestrum were removed and healing took place A year after the original operation a dense mass of new bone occupied the place of the graft

In the second case a single stout "cricket bail" graft was inserted into a gap fracture of the radius Chronic suppuration resulted, with the formation of two sinuses The X rays clearly showed that a portion of the graft formed a sequestrum, but that there was abundant new bone around it A later figure showed the restoration of the radius after the dead portion of the graft had been removed

This behaviour of a living autogenous graft in the presence of sepsis is, I believe, intimately associated with the preservation of the periosteum of the graft Although I have seen a naked graft heal in position without any periosteum, this has only taken place when the wound has run an aseptic course Moreover, there has never been any appearance of a sheath of new bone by which the graft has been increased in thickness, in fact the naked live graft behaves exactly in the same way as a bit of beef bone. But in the cases just related and in many others where periosteum is used there is an abundant formation of peripheral new bone, and if sepsis occurs there is usually a separation of a sequestrum from the graft.

This is readily explained without assuming any osteogenetic function for the periosteum. The periosteum is a vascular connective tissue membrane which readily establishes vascular connexions with the tissues into which it is transplanted, and it thus serves to link up rapidly the blood-vessels of the graft with those of its bed. Then, if inflammation occurs, the cellular elements of the bone survive where they are free to multiply on its surface, but die in the labyrinth of the Haversian canals where they are choked; in fact, the process is exactly the same as that which occurs in the course of a subacute osteomyelitis.

FIG. 4.



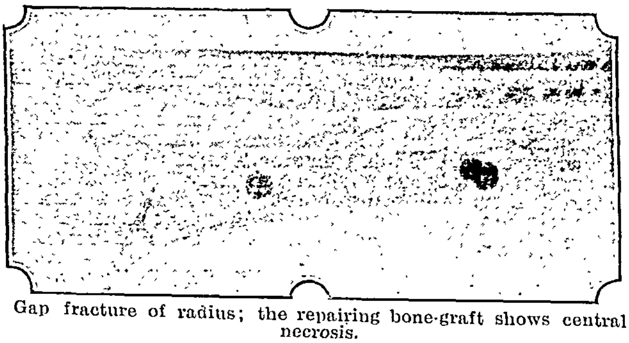
Gap fracture of radius treated by "cricket-bail" graft one year after operation.

The Vital Characters of the Tissues of the Bed into which the Graft is Laid.

These may be considered under the three headings: 1. Latent sepsis in scar tissue. 2. Atrophy of the bone ends. 3. Sclerosis of the bone ends.

1. *Latent sepsis.*—It will not be necessary to dwell on this subject at any length, because it has been so fully discussed in numerous papers dealing with post-war surgery. To some extent it is the most difficult factor in the whole situation, because it is so elusive. At one time it was thought that mere passive delay for a few months would enable the tissues to carry out an auto-sterilisation. But this is often a fallacy. For months, or even years, after a septic gunshot wound, particularly when this has involved the bones, the germs of sepsis lie dormant in the scar tissue ready to spring up to renewed youth and activity if circumstances become favourable. In particular, the streptococci and the *Bacillus coli* behave in this manner and are always ready to wreck the best-laid scheme of bone-grafting. Better than passive waiting for auto-sterilisation is the plan of a careful excision of scar tissue from the bed of the future graft, together with removal of the ragged ends of the broken bone and the replacement of cutaneous scars by pedicled skin flaps from other parts of the body. But this is a very difficult process to carry out in such a way that fresh infection of the tissues does not occur, so that ultimately nearly every bone-graft operation performed for an originally septic wound has to combat some degree of latent sepsis.

FIG. 5.



Gap fracture of radius; the repairing bone-graft shows central necrosis.

In such combat the tissues themselves will be the most powerful agent for recovery, and it is therefore very important that complete hæmostasis, absolute immobility, and absence of any "dead" spaces should be ensured. In this matter it is a question of minute care in tying vessels, suturing the tissues in layers, fixing the graft to the bones so firmly that no movement is possible, and providing for the immobilisation of the limb so that dressings can be done without any disturbance thereof.

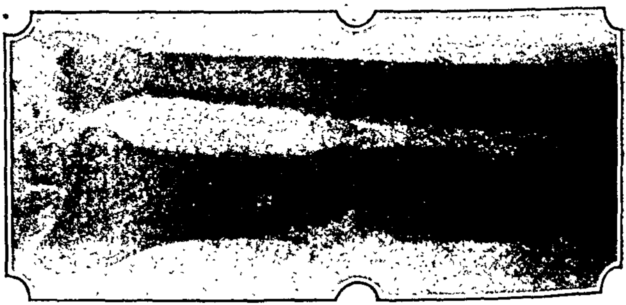
2. *Atrophy of the bone ends.*—In every gap fracture when the ends of the bone have been prevented from coming into contact by the presence of a companion bone (for example, in the forearm or lower leg) or by axial traction the bone undergoes a rapid atrophy. This atrophy is of a perfectly constant character, which has an important bearing upon the mechanical question of repair. It consists chiefly in the absorption of the bone salts and a disappearance of the inner portions of the shaft. Under the X rays the bone appears very transparent; when it is exposed and the end cut off the marrow cavity is much enlarged and filled with soft yellow fatty tissue. After some time it is reduced to a mere shell, so thin that in the bones of the forearm it can easily be crushed by a carelessly applied forceps or even by pressure between the thumb and finger. However much the atrophy, the outside diameter of the bone remains of its original thickness, and at the periphery a thin layer of dense bone is always preserved. Such a bone retains a certain degree of strength simply by virtue of its tubular character. If the tube is destroyed by cutting a piece out of its wall it will split or collapse. Nothing can be screwed to the outside of such a bone, because there is no substance on which the screws can take hold, and if a bolt be passed right through, the tube will collapse if any pressure be made from side to side.

If a graft has to be fixed to such an atrophied tubular bone there is only one way in which this can be done with mechanical efficiency, and that is by preserving the periphery of the tube intact and driving the graft into its cavity.

3. *Sclerosis of the bone ends.*—If the ends of the bone are not kept apart by a companion bone or by traction they rub against one another, and if callus union does not occur they undergo a thickening and sclerosis with the formation of a fibrous union or a false joint.

Under these circumstances the bone ends become of ivory hardness, the vascular canals being filled with new bone and the periphery being thickened by osteophytic outgrowths. Although in one sense such a condition represents overgrowth of bone, it is in reality a type of scar tissue in which vascularity and living cells are reduced to a minimum, whilst inert fibrous tissue and bone salts are present in excess. The main practical consideration is that the sclerosed bone end, as much as the atrophied, is a morbid condition and that the structure which is responsible for non-union of the fracture will equally prevent union with a graft.

FIG. 6.



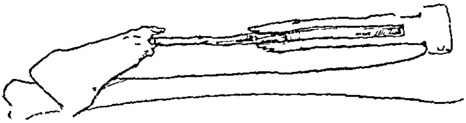
The same case as Fig. 5 one year later, showing massive regeneration of new bone.

These facts lead to the consideration of the operation of the sliding graft when applied to the treatment of an ununited fracture. Fig. 7 is from such a case and is quite typical of the failure which usually attends such an operation. It is from a gap fracture of the radius; a piece of the proximal fragment, about 2½ inches long, had been cut by a twin saw and slid down to a groove in the distal fragment. No union had taken place six months later, and the patient declined any further operation. The graft in such an operation is taken from the most unhealthy and indolent portion of the bone, and it is laid into a bed composed of similar tissues. Moreover, it is so small in size that it cannot act as a strut to the broken bone, which itself is weakened by its loss.

The Technique Employed in Bone-grafting for Ununited Fractures.

General and preliminary technique.—Certain preparatory operations have usually to be performed after the wound has soundly healed. These are: (*a*) Replacement of adherent or thin cutaneous scars by pedicled flaps containing skin and fat taken from the chest or abdomen in the case of the arm or from the opposite limb in case of the leg. (*b*) The excision, after a few months, of all deep scar tissue, including the unhealthy ends of the bone fragments. A culture is taken from this scar tissue, and if a positive result is obtained a vaccine is prepared and given to the patient in suitable doses for a period of about six weeks. (c) About two months later, if the preliminary operation healed smoothly, and about six months after healing if sepsis was awakened, the bone graft operation is undertaken.

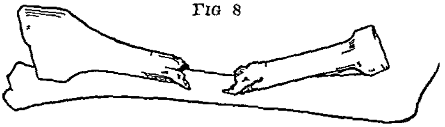
FIG 7



Failure of sliding graft applied to gap fracture of the radius

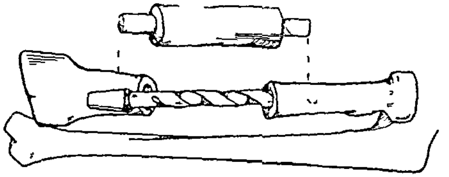
The method by which immobilisation of the limb after the operation is to be secured must be carefully arranged beforehand. The use of plaster of Paris at the time of operation is subject to several serious disadvantages. There is usually much oozing after these operations, and this will make the plaster case foul. A window may be cut over the wound at the time, and by packing in pieces of cellular rubber sponge the serum is to some extent prevented from running between the limb and the plaster. But I am distinctly in favour of postponing the application of plaster until all oozing has ceased. The humerus is the most difficult bone to fix. The best plan is to make a plastic splint of buckram and glue, which should take a broad bearing from the chest and iliac crest and also support the arm in full abduction. To this splint the patient should have become familiarised for several weeks before the operation. In the case of the forearm an internal angular splint with a "cock up" rest for the hand is sufficient for the first week, and then a plaster or two piece moulded splint can be fitted. For the thigh a Thomas splint cradle splint, or a sling to an over head beam is sufficient for the first period, and at the end of a week plaster-of Paris as a spica or a moulded splint should be used. For the leg below the knee a bent Thomas splint or Macintyre is best for the first stage, followed by a plaster case. The whole limb is shaved and painted with 3 per cent picric acid in spirit. At the time of operation it is covered by a piece of sterile stockinette, through which the incisions are made. The edges of the skin incision are fastened to the *stockinette by Michel's clips. No tourniquet is used.* The surgeon wears cotton gloves over rubber to obviate the danger of the latter being torn. All blood vessels are picked up and tied with fine catgut. Oozing from bone surfaces if excessive, is controlled by the use of Horsley's wax. The utmost care is taken to close the wound in layers so that the bone may be well buried in muscle, and this in turn covered by fascia and skin. The more deeply the bone is buried the less likely is it to be affected by secondary infection from the skin. Also deep suturing controls oozing and prevents "dead" spaces. When in spite of all care oozing is well marked a drain of silkworm gut is used and removed in 24 hours.

FIG 8



Gap fracture of radius with displacement over ulna

FIG. 9

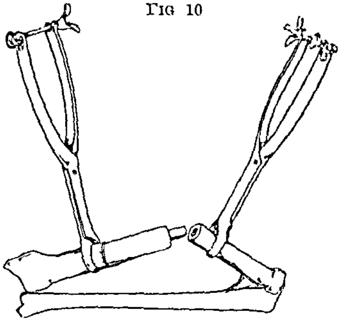


Fragments of radius (shown in Fig. 8) brought into alignment both ends being drilled to receive the pegged ends of the graft

The Bones of the Forearm

The following remarks apply for the most part to the radius. A loss of continuity in the ulna produces so little functional change, that it is questionable whether a grafting operation is justifiable for this defect. If, however, the ulna has to be repaired, the steps of the operation are similar to those undertaken for the radius. There are two operations which have been suggested *for a gap fracture of one of the bones of the forearm* when the other is intact, as alternatives to a tibial graft. *If* there is, for example, an inch gap in the radius, it has been suggested that the ulna should be shortened by rather more than 1 inch and united by some kind of a "step cut" operation. In my opinion there is only one condition which justifies this procedure, and that is the loss of the flexor or extensor tendons at the site of fracture. Under these circumstances shortening the forearm will enable a restitution to be made of the tendons. If this operation is to succeed the shortening of the ulna must be carried out to such an extent as to allow of a free removal of the indolent ends of the radius, because if the latter are merely brought into apposition without refreshment non union will certainly persist. The other operation which has been suggested, of which I have seen some examples, is the removal of a segment from the ulna and the implantation of this segment into the gap of the radius. This is much more difficult than the tibial graft described below, and it is subject to the great disadvantage that the firm splint provided by the intact ulna is lost.

FIG 10



Graft being fitted into its bed by eversion of the fragments

FIG 11

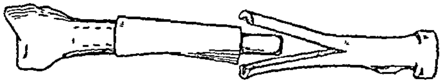


FIG 12.

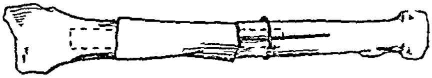


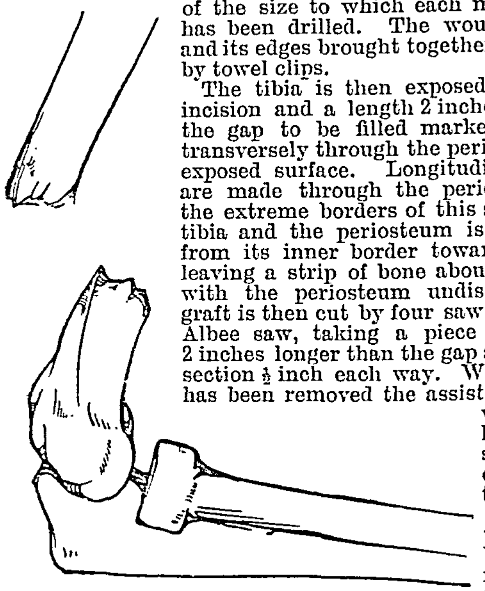
Gap fracture of the radius grafted from the tibia showing one end of the radius split and wired

The "cricket bail" graft.—After trying various types of graft fixed to the surface of the fragments, with a varying degree of success, I have *adopted the use of a graft shaped* like a cricket bail, *cut from the crest of the patient's own* tibia and this has given such successful results that I now use it always *for mending gap fractures of the forearm bones.* The bed for the graft is first prepared by exposing the fractured ends of the bone, freely cutting away the irregular or conical ends, while exposing or baring their surfaces as little as possible.

Each fragment is bluntly separated from the adjacent bone when tied down by adhesions of the interosseous membrane. The fragments should be mobilised freely enough to allow of the end of each being brought well up into the wound. This is not merely for convenience at the subsequent operation, but in order to separate the central parts of the shafts of the radius and ulna as widely as possible one from another. When this has been done each fragment is bored by as large a twist drill as can be driven into it easily—i.e., without cutting away anything more than soft marrow or friable bone. The shaft of the radius usually admits of a ¼ to 5/16 inch drill being employed for this purpose, but the lower end is considerably larger. In dealing with a fracture about 2 inches above the wrist it may be necessary to scoop out the cavity of the lower fragment by means of a small chisel into a hole oval in cross section ½ inch by ¾ inch. The actual size of the hole does not matter so long as a strong sound shell of bone is left into which the cricket-bail graft can be firmly driven.

The depth to which the ends are drilled is not very important; usually it should be about 1 to 1½ inches. Careful note is made of the length of the gap left after removal of the bone ends and of the size to which each marrow cavity has been drilled. The wound is packed and its edges brought together temporarily by towel clips.

FIG. 13.



Gap fracture of the lower end of the humerus.

The tibia is then exposed by a curved incision and a length 2 inches more than the gap to be filled marked by cutting transversely through the periosteum on its exposed surface. Longitudinal incisions are made through the periosteum along the extreme borders of this surface of the tibia and the periosteum is turned back from its inner border towards the crest, leaving a strip of bone about ½ inch wide, with the periosteum undisturbed. The graft is then cut by four saw cuts with an Albee saw, taking a piece of the crest 2 inches longer than the gap and of square section ½ inch each way. When the graft has been removed the assistant closes the wound in the leg, whilst the surgeon proceeds to shape the graft.

The periosteum is turned back for 1 inch from each end, the graft is wrapped in a piece of tetra cloth which leaves the end free for 1 inch, and placed in a small vice. The bare end is cut down by the Albee saw to something near the size of the marrow hole it has to fit. The angles are then filed and the end is passed through the holes of a reaming plate, these holes corresponding to the size of the drill used. The other end of the graft having been treated in a similar manner there remains a piece of bone consisting of a central stout portion, the length of which corresponds to that of the gap in the radius, and two rounded ends, each 1 inch long, the thickness of which is that of the holes in the fragments. To the thick part of the graft a piece of periosteum is attached, with an abundant free margin laterally and at each end.

The wound over the radius is now reopened. The distal fragment of bone is grasped by a suitably curved bone-holding forceps and brought out into the wound. The graft is driven into this, and the projecting cuff of periosteum is sewn round the junction between the graft and the radius. Next comes the critical stage of the operation. The easiest and neatest way to insert the proximal peg of the graft is to lever outwards the proximal fragment of radius after cutting the peg to ½ inch in length. The graft is made to engage in the hole of the upper fragment and slowly the two are pressed back into alignment. (Figs. 8, 9, 10.) The peg slips into its place with a "click," and for the moment all is well, the periosteal cuff being treated as before. But though this is the neatest way of finishing the operation, it is open to one objection, which is that the upper peg is so short that it does not serve to keep the graft and upper fragment in alignment, and there is a tendency for the radius to "sag" inwards towards the ulna at this point.

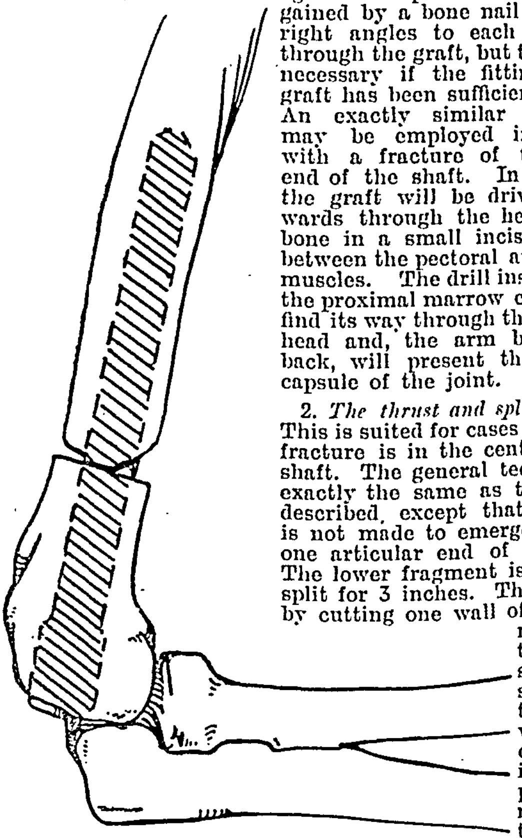
The more efficient way of completing the fitting of the graft is to split the proximal fragment of the radius by the motor-saw for 2 inches. (Fig. 11.) The split is then cautiously prised open and the peg end of the cricket-bail placed in position. The end of the radius is then tied together with a double turn of fine iron wire. (Fig. 12.)

The Humerus.

The humerus presents one of the most difficult problems of repair. Very special care is required in immobilisation, because if this is not done and the arm is left hanging by the side it will drag on the graft. Moreover, the shoulder-joint is apt to become very stiff and each movement of lifting or rotation of the arm puts a great strain on the graft and its fixation. Three types of graft-fixation may be used for the humerus which may be described as the thrust, the thrust and split, and the two-piece graft.

1. *The thrust graft.*—This graft is specially indicated for cases without much loss of substance, but in which there has been so much absorption atrophy that the ends are too fragile for a "step-cut" union. In principle it consists in nailing the two fragments together by means of a stout intra-medullary nail. Take, for example, the case shown in Figs. 13 and 14, where there has been a gap fracture at the lower end already treated without success by a plate. The region of the fracture is exposed by an incision over the external intermuscular septum. Each fragment is refreshed and the ends so shaped as to fit snugly against one another. when the bone is aligned. Then each end is brought out into the wound and drilled for 3 inches by a twist drill, usually by one about ½ inch in diameter. The distal fragment is drilled last, and the elbow being acutely flexed the drill is thrust right through the elbow-joint and out of the skin. This external opening is temporarily plugged by a pair of artery forceps which serve to keep it patent. The graft is now prepared from the tibia unless a beef bone is being used. In either case the graft is 6 inches long and rather more than ½ inch thick, and roughly cylindrical in shape with one end slightly pointed. The pointed end of the graft is thrust into the opening at the tip of the elbow, the margins of which are held apart by four pairs of tissue forceps. It is then hammered into place. When its point has reached the gap of the fracture it is adjusted into the mouth of the marrow cavity of the proximal fragment, and the arm is brought into correct alignment with proper orientation as regards rotation of the forearm upon the arm. The graft is then hammered home until its lower end is clear of the condylar region of the humerus. Extra security against displacement may be gained by a bone nail driven at right angles to each fragment through the graft, but this is not necessary if the fitting of the graft has been sufficiently tight. An exactly similar technique may be employed in dealing with a fracture of the upper end of the shaft. In this case the graft will be driven downwards through the head of the bone in a small incision made between the pectoral and deltoid muscles. The drill inserted into the proximal marrow cavity will find its way through the humeral head and, the arm being held back, will present through the capsule of the joint.

FIG. 14.



The same case treated by means of a "thrust" graft.

2. *The thrust and split graft.*—This is suited for cases where the fracture is in the centre of the shaft. The general technique is exactly the same as that above described, except that the drill is not made to emerge through one articular end of the bone. The lower fragment is carefully split for 3 inches. This is done by cutting one wall of the fragment by the motor-saw and splitting the deep wall by a chisel. It is very important not to bare this part of the bone by separating its covering of soft parts from it. The graft is then hammered into the proximal fragment for 3 inches and laid between the split halves of the distal fragment. These halves are then brought together and fixed by a double turn of soft iron wire.

In both these types of operation the graft is, of course, bare of periosteum, as it has to lie entirely buried in the marrow cavity of the humerus.

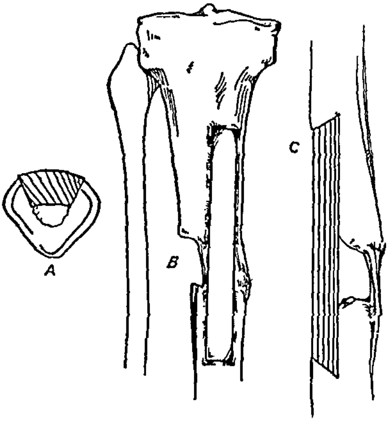
3. *The two-piece graft.*—If there has been such a great loss of substance of the bone that the two ends cannot be brought into apposition it will be necessary not only to fix the graft into each fragment, but also to bridge the gap in such a way as to give the best chance of new bone growth in this interval. Two grafts are taken; one is driven firmly into each fragment and the two grafts are then united to one another in the gap by bolts or wire. In a gunshot fracture requiring an autogenous graft it is necessary to

cut two tibial grafts, or one long one which can be cut into two Each has ample periosteum attached to it The periosteum is turned back from the end driven into the marrow cavity, and this membrane is then wrapped round the line of junction between fragment and graft The two grafts being united by two bolts or wires there will be a double thickness of graft in the gap, and this will be entirely covered in periosteum

The Tibia.

The tibia presents special difficulties of its own The bone is to a greater extent than any other long bone subcutaneous, and this means that scars of wounds are usually adherent to, or are immediately over, the seat of fracture Further, in adults the bone is dense and avascular, and not suitable for rapid callus repair Two separate conditions require consideration, firstly, an ununited fracture without much loss of substance, and, secondly, a typical gap fracture

FIG 15



Gap fracture of the tibia united by an "inlay" graft (B) At A and C are shown the section and side elevation of the graft

1 *Fracture without loss of substance* (Fig 15)—It is here more absolutely essential than anywhere else to replace all scars by healthy skin, so as to leave no cicatricial tissue over the seat of operation At a suitable period after this has been done the bone is exposed by a long curved flap Two aluminium templates are used to measure the graft and the bed in which it is to lie These measure 6 by ½ inch and 6⅛ by 9/16 inch respectively, *the longer and wider one being* used as a guide in cutting the graft, whilst the smaller is for the bed Each template is provided with four small holes for tacks, the plate being temporarily nailed in place whilst the motor saw cuts along its edges The fractured bone being exposed the periosteum is raised from an area 6¼ inches long in the middle of the anterior surface by a central longitudinal incision and cross cuts at each end, two flaps being turned aside The smaller template is fixed in position, and the bone underlying it cut out by four saw cuts The lateral saw cuts converge towards the axis of the bone, the end cuts undercut the bone, whilst all go deep enough to penetrate the marrow cavity By means of a chisel the bits of bone thus marked out are raised from the bed, and a cavity for the graft is left The graft is cut from the opposite tibia In this case the periosteum is cut by a rectangular incision ¼ inch wider and longer than the graft and turned inwards The periosteum so conserved is protected by the template nailed in position and the graft is cut If the ends have been properly undercut it will be necessary to remove a wedge shaped piece of bone at one end in order to free the graft, which is then raised by a chisel, with the template still attached The graft is then placed in its bed The width of graft and bed ought to correspond exactly, because the wider template used as a gauge for the former allows for the bed being two saw thicknesses wider than the smaller template The shape of the ends is such that the deep surface of the graft is longer than the superficial By traction on the leg the length of the bed for the graft is temporarily lengthened the graft is then hammered down into position and the two parts of the tibia are forced together so as to lock the graft in position The edges of periosteum of the bed are then sewn to those of the graft, and the skin flap is closed

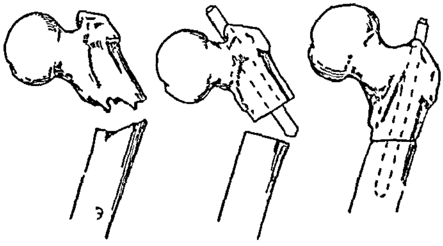
2 *The gap fracture*—If a gap of 1 or 2 inches exists in the tibia the choice will lie between shortening the fibula so as to bring the tibial fragments into contact, and filling the gap by a graft If the gap is more than 2 inches a graft is the only alternative to amputation The best type of graft to use for such a long gap is a homogenous one taken from a clean fresh amputation, if such be available The graft should be prepared, with its periosteum in place and a *projecting cuff to cover the line of junction between graft* and fragments Two projecting tongues of bone are cut at each end of the graft and fitted into corresponding slots in the fragments

The Femur

In the case of a large gap in the femur, involving more than 3 inches of shortening of the leg, it is generally wisest to advise amputation, because in such cases there is usually much concurrent injury to muscles and nerves and the leg as a whole is much atrophied Practically every ununited fracture of the femur must be joined with end to end apposition of the fragments, as it is not possible in the adult to fill up a gap with a graft sufficiently firm to take the body weight

The thrust intra medullary graft (Fig 16)—For the shaft of the femur strong round pegs ½, 7/16, and ⅜ inch thick and 6 inches long should be prepared from beef bone or ivory It is very difficult to get a solid piece of beef bone more than ½ inch thick, and I prefer ivory because of its greater strength The site of the fracture is exposed, the ends brought out into the wound, refreshed and bored by drills up to ½ inch in diameter A special long drill is run up the proximal fragment until the tip of the great trochanter is pierced A steel rod 12 inches long and ⅜ inch thick, with a pin at its lower end fitting a hole in the upper end of the peg, is passed up the proximal fragment until it can be felt through the skin of the buttock, where it is cut down upon and thrust out The peg is then fitted to the rod and driven up the femur until only ½ inch is left projecting at the site of the fracture The fragments of the fracture are adjusted and the peg is hammered down into the lower fragment until it lies equally in the two fragments It is very important that the hole drilled in the fragments should be smaller than the size of the peg (a ⅜ inch hole will suffice for a 7/16 inch peg), the rarefied inner layers of the bone readily admit of a peg being forced into a small hole, and it will then be absolutely tight If the fracture be at the upper end of the femur the peg can be inserted from the tip of the trochanter instead of being passed up the canal of the proximal fragment

FIG 16



Ununited fracture of the upper end of the femur showing insertion of peg into the upper fragment and driven down into the lower

There are two situations in which a bone graft may be used for a femoral fracture One is in the neck and the other in the shaft About the former operation it is not necessary to give details, because this has been long recognised as the best treatment for non union of the neck Only two points need be mentioned One is that the site of the fracture should always be exposed by an anterior incision such as that used for excision of the hip joint This is necessary to secure correct orientation of the fragments and proper direction for the graft, and it also enables the operator to refresh the line of fracture by the removal of interposing fibrous tissue The second is that, whether the graft be beef bone or fresh human tibia, it should be cut roughly square—a ½ inch square—and driven into a ½ inch round hole The cancellous tissue permits of this quite readily, and a firmer union results than from the use of a round peg in a round hole

NOTES ON A CASE OF
RESECTION OF TIBIA WITH GRAFTING.
WITH PLATING OF FRACTURED GRAFT.

BY L. E. BARRINGTON-WARD, CH.M., F.R.C.S. EDIN., F.R.C.S. ENG.,

SURGEON (IN CHARGE OF OUT-PATIENTS) TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, AND GREAT NORTHERN CENTRAL HOSPITAL.

IN the operative treatment of chronic osteomyelitis of a long bone two alternative lines of treatment are available. Chronic osteomyelitis is not here taken to mean the chronic condition resulting from the unsuccessful treatment of acute osteomyelitis, but quiet bone inflammation of staphylococcal, pneumococcal, or tuberculous origin. (These are, as a rule, indistinguishable clinically and radiographically, and in most cases can only be differentiated after bacteriological examination.) The oldest method is the simplest, the most generally used, and perhaps the least efficacious. An incision is made over the affected bone, the medullary cavity is opened up, diseased bone is removed by gouge and forceps until healthy limits are reached, the resulting cavity is disinfected thoroughly, the soft parts are brought together, and the wound is closed.

The second method has been most strongly advocated and developed by Stiles of Edinburgh. This is more radical, and the diseased shaft is removed entire. By appropriate splinting the limb is kept in good position, and in the course of time the diaphysis is reproduced in healthy bone.

The Method Used.

A third method is a modification and, I believe, an improvement on the simple resection. It consists in excision of the affected shaft through healthy limits and inserting a bone-graft—generally obtained from the tibia—into the gap so made. This transplant is cut to the exact length required, and is fashioned and fixed as an efficient internal splint, rendering unnecessary the subsequent use of cumbrous apparatus, and helping to some extent in the regeneration of bone. It is also possible that the fresh healthy bone cells of the graft may assist in dealing with any of the original infection —for example, of the periosteum—which has inadvertently or unavoidably been left behind.

Various grafts have been suggested—the tibia from a recently amputated leg, the fibula of the same patient. Such complications are unnecessary. A strip from the patient's healthy tibia fulfils all requirements, is easily cut with simple instruments, and has no ill-effects on the donor. It is not necessary to take periosteum with the graft. The true periosteum is a limiting membrane, and, provided the periosteal tube is left to receive the graft, the perfect shape of the bone will be reproduced. I have employed this method with complete success in treating osteomyelitis of the humerus, radius, ulna, and tibia. The following case illustrates the method in the case of the tibia, but it is recorded rather to show the behaviour of the graft under trying circumstances.

The patient, a girl aged 6, came under my care at the Hospital for Sick Children, Great Ormond-street, in March, 1914. She had a swelling of the middle third of the tibia, which had been noticed for a year. There was no history of injury. The Wassermann reaction was negative. X ray showed a dense osteitis of the shaft of the right tibia. At operation on April 2nd the sclerosed bone was opened up and an abscess cavity was found in the centre. The pus was sterile, and no tubercle bacilli could be found. The diseased bone was removed as far as possible, the cavity disinfected, and the wound closed without drainage. The wound healed satisfactorily, and progress was uninterrupted until July, 1914. A recrudescence of activity was then noticed, the bone becoming more swollen and tender. She was again admitted, and an operation was performed at a demonstration before the American Congress of Surgeons.

The original scar was excised and about 6 inches of the tibial shaft, including all the diseased bone, was resected subperiosteally. The medullary cavity at each end was reamed out and careful measurements were taken. A graft was then cut of the required length and size from the normal tibia and shaped to fit the gap exactly. Each end of the graft was rammed firmly into the reamed out medullary cavity, a shoulder being fashioned at either end to ensure correct length. The wounds were closed and the leg put in plaster. X rays from time to time showed the good progress of the transplant. It would seem that growth was taking place chiefly from the cut ends of bone along the scaffold graft. By February, 1916, the patient was walking about without a splint. In March, 1916, she fell over a railing and snapped the graft across. She was readmitted to hospital and the fracture was accurately set by open operation and plated by Lane's method. Subsequent history was uneventful. She was allowed to walk freely four months later. When last examined (September, 1919) she had a normal right leg, equal in length, size, and strength to the left, and perfect function.

Remarks.

This case illustrates some interesting points in the question of bone regeneration. The opportunity was taken when the fractured graft was plated to make a careful examination of the twenty-month-old transplant. The graft was tapered from either end and had broken at its thinnest part—the middle. It would seem that most of the growth had taken place at the ends, and that bone had grown down and up along the graft. There was no evidence yet of a medullary cavity. The texture of the bone was firm and the screws gripped well. In the growth of the transplant since the plating the plate has remained on the surface, showing that the increased thickness was not due to deposition of bone by the periosteum.

The fracture, as is usual with plated fractures, healed without external callus. The last X ray, five and a half years after the original operation, showed perfect reproduction of the shaft with restoration of the medullary cavity and no trace of graft or fracture.

A CLINICAL STUDY OF
INFECTIONS OF THE HAND.

BY H. W. L. MOLESWORTH, F.R.C.S. ENG.,

SENIOR HOUSE SURGEON, POPLAR HOSPITAL FOR ACCIDENTS.

LITTLE has been written in English publications on this important subject, which has, however, been reviewed very completely in America by Kanavel—an author too little known in this country. This investigation has been made in order to show how the graver hand infections commence and to ascertain whether these severe lesions are preventable by early appropriate treatment. As certain facts have been observed which, though not bearing directly upon this matter, may be of interest, the paper has developed into a brief account of infections of the hand as seen in those who earn their living with their hands. Every available case, trivial or otherwise, was seen, notes were kept, and treatment was either supervised or carried out by the writer; the severer cases were admitted to beds which were under his direct observation. I should like to compare the results in this series of cases with those obtained among the nursing staff of a large institution, where cases report sick early, and consequently get early and thorough treatment.

Anatomy.

In order that the descriptions of fascial space infections may be understood the briefest possible account of the anatomy is given, as this is not well described in text-books of anatomy. Those who wish will find an extremely full account in Kanavel's "Infections of the Hand."

There are six well-defined spaces which are liable to become infected.

1. Dorsal subcutaneous. 2. Dorsal subaponeurotic. These two spaces on the dorsum of the hand and fingers are sufficiently well described by their names.

3. The middle palmar space. This lies deep to the flexor tendons and superficial to the metacarpals and interossei; it is limited on its radial side by a layer of fascia at the level of the third metacarpal bone. It is

liable to become infected from the tendon sheaths of the third, fourth, and fifth digits, or by the lymphatics, and can best be drained through an incision into the distal part of the third or fourth intermetacarpal spaces, thence by Hilton's method.

4. The thenar space. This lies between the adductores pollicis and the superficial thenar muscles, it is separated from the middle palmar space by the layer of fascia mentioned above. It is liable to become infected from the index, rarely from the middle, and still more rarely from the thumb flexor sheaths, or by lymphatic spread. It is best drained by an incision parallel and dorsal to the web in the first interosseous space; from here a pair of pressure forceps are thrust in the direction of the base of the first metacarpal bone.

5. The lumbrical spaces, of which there are four. These form a channel from the flexor profundus tendons in the palm to the radial sides of the dorsum of their respective digits. They normally convey the lumbrical muscles, but not infrequently convey pus to the dorsal part of the web. They are best drained by short deep incisions into the palmar part of the web; this incision, if necessary, may divide the web without causing disability.

6. The hypothenar space. This is superficial and of little importance.

Treatment.

The moment that the presence and site of pus has been diagnosed free drainage must be provided. Fluctuation is a late sign of suppuration as met with in the hand; it should never be waited for. The site of maximum tenderness is of far greater value in estimating the site of pus than the site of maximum swelling. Tubes, gauze strips, and strips of rubber are unsatisfactory as means of promoting drainage; they often hinder it, and, in addition, encourage sloughing of the tissues. Large incisions which gape save time in the end by giving free drainage without the introduction of foreign bodies. With free incisions the nature and the frequency of dressings matter very little. Fomentations were nearly abandoned with, it was thought, a marked improvement in results; the solitary advantage—that of relieving pain—is short-lived, and is outweighed by the many disadvantages which include cross infection, sodden hands, and, worst of all, the fact that the use of fomentations is too often the substitute for efficient drainage. It was observed that cases did not need frequent changes of dressings. A voluminous gauze dressing is much more absorbent than a wet dressing, and sometimes a case which had no attention for several days did just as well under its pus-soaked dressing as cases which had had daily dressings. This only applies to cases where drainage is really free.

Hypertonic saline baths were certainly beneficial.

Case Grouping.

The cases fall most naturally into the following groups:—

Group I.—(1) Perionychia (infections around the nail); (2) abscess in the pulp of the finger; (3) abscess on the palmar aspect of hand and fingers. These three constitute the most important primary infections.

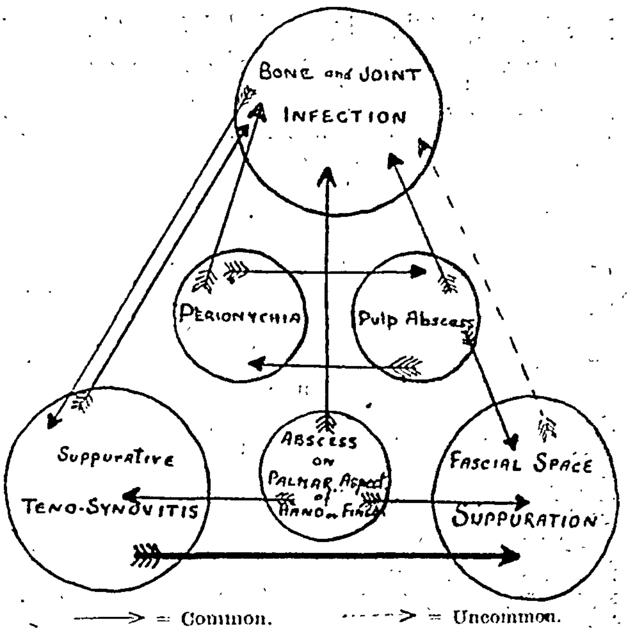
Group II.—(4) Suppurative tenosynovitis; (5) bone and joint infections; (6) fascial space abscess in palm and forearm. These constitute the most important grave secondary infections.

Group III.—(7) Abscess on the dorsum of the hand and fingers; (8) "carbuncular infections"; (9) trivial infections (chiefly subcuticular abscess); (10) lymphangitis and glandular abscess; (11) cellulitis.

The lesions in Group I., whilst remaining in that group, are relatively trivial; but they readily give rise to the Group II. infections, which are responsible for nearly all the cases of severe crippling.

The possible modes of spread are indicated by the arrows in the following diagram. Group II. infections are rarely primary; severe crushing injuries seem more prone to give rise to the cellulitis type of infection than to the clear-cut infections with which we are mainly concerned here.

Diagram showing Possible Modes of Spread.



Bone and Joint Infection
Perionychia
Pulp Abscess
Suppurative Teno-Synovitis
Abscess on Palmar Aspect of Hand or Finger
Fascial Space Suppuration
⟶ = Common.
- - - -> = Uncommon.

Perionychia.

Number of cases	30	
Average number of days disabled	7·4 days.	
Pus present when first seen	28 cases	= 93·0%
Pus under the nail	19 „	= 63·0%
Necrosis of bone	2 „	= 6·6%
Pulp abscess	5 „	= 16·6%
Tenosynovitis	0 „	= 0·0%
Source—Splinters, needle pricks, &c.... ...		43·0%
„ Uncertain (probably cracks in skin)		57·0%

Perionychia is thus not a very prolific source of grave infections—it is a possible cause of any of the three graver infections, but the chief serious complication is undoubtedly infection of the terminal phalanx.

Treatment.—Gas anæsthesia is necessary for efficient treatment. The whole nail should not be removed unless it is completely undermined by pus. In early cases, in which there is no pus under the nail, the best operation has been to make a series of about five short deep incisions radiating from the nail base. (Fig. 1.)

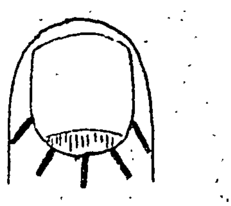


FIG. 1.—Operation for perionychia where there is no pus under the nail. Five short deep incisions radiating from the nail base.

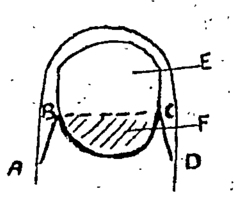

FIG. 2.—Kanavel's operation for perionychia where the nail is undermined by pus at its base. E, Portion of nail retained. F, Portion of nail removed.

In cases where the nail is undermined by pus at its base the operation described by Kanavel has given extremely satisfactory results. A flap, A, B, C, D, is dissected back, the base of the nail is divided with scissors along the line B, C, and the proximal portion is removed. The old nail, or rather its remnant, still exercises its protective function whilst the new nail is growing. (Fig. 2.) In extensive cases the whole nail must be removed, involving a longer period of disablement.

Abscess in the Pulp of the Finger.

The dense fibro-fatty tissues of the pulp have a close connexion with the periosteum of the terminal phalanx; this was attributed by Kanavel to the fact that here the glands of the skin penetrate as far as the periosteum. Infection of the terminal phalanx is the chief complication to be feared in this condition. Acute tenderness with induration of the pulp are sufficient signs of abscess, and fluctuation should not be waited for. Directions of spread: (1) To the terminal phalanx; (2) to the nail bed, (3) to the flexor sheath; (4) by lymphatic spread to the hand, forearm, arm, and axilla.

Treatment.—Incision to be efficient requires gas anæsthesia. The incision should be made at the side to avoid a scar where tactile sensation is most important and should be long enough to gape.

Number of cases	37
Average duration of disablement	11·5 days
Average duration of disablement in uncomplicated cases	6·0 ,,

Abscess on the Palmar Aspect of the Hand and Fingers

This group of cases showed what appeared to be the commonest mode of infection of the flexor synovial sheaths, and it is in this group that early thorough treatment will save many hands from becoming crippled.

Source of infection.—Superficial cuts, needle pricks, splinters, and, most common of all, infection occurring under a corn or wart. The two strikingly common sites were. (1) the "rowing blister area" in front of the heads of the metacarpals (15 cases), (2) the palmar aspect of the fingers

The first group of the above infections may spread (*a*) towards the base of the flexor synovial sheath (14 cases); (*b*) towards the lumbrical spaces (forming the "collar-button" abscess) (5 cases); (*c*) towards the middle palmar and thenar spaces (1 case).

The second group of infections may spread (*a*) towards the flexor synovial sheath; (*b*) towards the spaces on the dorsum of the finger.

Number of cases	35
Average period of incapacity	9 days

Three cases had involved but had not perforated the flexor sheath, which seems for a time to offer a barrier to the spread of infection. These cases all healed rapidly when drainage was established.

Diagnosis.—The symptom is throbbing pain. The signs may resemble very closely those of tendon sheath infection. Flexion of the finger, pain on movement, swelling of the finger, and tenderness over the sheath may all be present, and the degree to which they are elicited varies with the patient's stoicism. A good guess can usually be made, but it is only a guess, and requires to be confirmed by careful exploration.

Treatment.—These cases require general anæsthesia (gas and oxygen is ideal), a tourniquet is necessary and an Esmarch bandage is an additional convenience. Open at the site of infection, follow the pus to all its pockets, and make sure of free drainage, if necessary, divide the web completely. If swelling of the sheath or the discovery of a communication between abscess and sheath show the existence of tenosynovitis the sheath must be opened. This type of hand infection is both common and important, in one or another of its forms it is responsible for more than 50 per cent. of the cases of suppurative tenosynovitis in the present series of cases. Every stage between a simple subcutaneous abscess and one that involves tendon sheath, fascial spaces, and bones and joints will be seen if cases are carefully explored in a bloodless field. If freely drained *at an early stage the results are excellent*

Suppurative Tenosynovitis.

Number of cases	16
Cases developing the complication of fascial space abscess (thenar space, 2, middle palmar space, 2, lumbrical space, 5, dorsal spaces, 6)	8
Infection of other sheaths	4
Bone and joint infection	4
Cause	
Wound of sheath	0
Pulp abscess (2 by way of necrosis of phalanx)	4
Abscess on palmar aspect (4 of these were due to superficial wound over interphalangeal joint)	10
Undetermined	2
Bacteriology	
Streptococcus pyogenes	8
Staphylococcus aureus	6
Mixed staph and strep	1
Undetermined	1

Tenosynovitis of this type is rarely or never a primary disease. There is always a preceding infection. This primary infection has been most commonly an abscess on the palmar aspect of the hand or of a phalanx. In 4 of the cases a superficial wound over one of the flexion creases led to infection of the sheath.

Pulp abscess is also a common cause, which may act in two ways: 1. Direct infection of the terminal portion of the sheath. 2 Infection of the phalanx and from this infection of the sheath (2 cases).

Perionychia did not cause any case of tenosynovitis in this series of cases, but since it may be the cause of either bone infection or pulp abscess it must be reckoned as a possible cause.

The outstanding *complication of tendon-sheath infection* is undoubtedly fascial space abscess, with which must be included direct spread into the forearm under the anterior annular ligament. This latter occurs in two ways: 1. Empyema of the synovial sac, which surrounds the flexor tendons in the palm, this sac consists of two divisions, an ulnar bursa communicating generally with the fifth flexor sheath and a radial bursa, or the sheath of the flexor longus pollicis 2. Middle palmar space abscess extending deep to the synovial sheath into the forearm The first of these usually ruptures at the upper end of the bursa and so infects *the same space in the forearm as the second.* Abscess in the forearm occurred in three cases.

Diagnosis.—The physical signs upon which a diagnosis of sheath suppuration is made are: (1) the general condition of the patient; (2) the combination of swelling and flexion of the whole digit; (3) pain on movement, particularly on extension; (4) exquisite tenderness over the sheath; (5) most important of all, a careful exploration of the site of infection.

Treatment.—General anæsthetic and tourniquet Open at the site of infection, this allows of the differentiation from palmar subcutaneous abscess in all cases The question of the amount to which the sheath should be opened is still one for discussion The two chief views are: 1. Open the sheath in its full length This is what has been done in the majority of cases in this series Drainage is as free as possible and the tendon does not necessarily slough 2 Open the sheath laterally over the phalanges, leaving the portions over the joints. This certainly prevents prolapse of the tendon, but this undesirable event can also be prevented by splinting the finger in extension When the tendon has a dull yellow appearance it will surely slough, much time can then be saved by excising it If the tendon is merely cut off the infected upper end will retract into the palm and will there cause a secondary abscess, a better plan is to fix both tendons to the periosteum of the proximal phalanx by a stitch which holds until protective adhesions are formed

It is most important to move all the fingers daily during the after treatment.

One observation is *of some interest* in this connexion There appears to be a type of low grade infection which, when one sheath is involved in an acute suppuration, occurs in other sheaths, pus is not formed but adhesions *develop which limit* the movements of the other fingers This was well shown in a dissection of the amputated limb in one case. On clinical grounds the presence of pus in two sheaths had been suspected. The patient's general condition demanded amputation. On dissecting the fresh specimen many recent adhesions but no pus were found The same clinical suspicion has arisen in other cases, but no opportunity for verification has arisen The limitation of movement remains as evidence that adhesions had occurred

Bone and Joint Infection

This condition must be distinguished from osteomyelitis of the bones in the hand, which is part of a staphylococcal septico pyæmia The bone infection referred to here appears to run a different clinical course, abscesses of a metastatic nature have not been met with, the condition is not confined to young subjects, it is always the result of direct extension of the inflammatory process.

Number of cases 17

Cause.

Pulp abscess	8	Perionychia	4
Tenosynovitis	4	Undetermined	1

Tenosynovitis was responsible for the cases which involved the proximal phalanges and joints.

Treatment is unsatisfactory; in the majority of cases necrosis of the whole, or nearly the whole, phalanx occurs, and the fact that 5 out of 17 cases were eventually amputated shows that the condition is one which leads to severe and crippling deformity. Very early cases which have a subperiosteal abscess may clear up without necrosis of bone if freely incised at once. This condition—primary subperiosteal abscess—was met with in one case only. The large majority of bone infections are secondary to an infection which is at first easily treated, but which, if neglected, leads to inevitable deformity.

Abscess on the Dorsum of the Hand and Fingers; Fascial Space Abscess in the Hand and Forearm.

Abscess on the dorsum occurred: (1) as a complication of tendon-sheath or bone infection; (2) as a result of a wound on the dorsum of the hand. Infections on the dorsum extend to the lymphatics and glands more often than do the palmar infections. On the other hand, it is the palmar infections which cause great local damage. Dorsal infections cause severe disability only when they result in spreading cellulitis. The treatment is free incision.

Fascial space abscesses.—(A) Middle palmar space: This space was infected in two cases, both from a tenosynovitis of the middle finger, and both spread deep to the flexor tendons into the forearm.

Diagnosis.—The sign described by Kanavel, which consists of swelling of the whole hand as compared with its fellow, is not sufficiently sharply defined to make for early diagnosis. It is better to depend on careful exploration of the site of infection. If, for example, during an operation for tenosynovitis of the middle finger pus is observed to be tracking deep to the tendons on the ulnar side of the hand, this opening must be enlarged and the middle palmar space freely drained. The habit of making every operation for an infected hand partake of the nature of an exploratory dissection is one which makes accurate diagnosis available for every case.

(B) Thenar space: This space was infected in four cases: (*a*) index tenosynovitis; (*b*) flexor longus pollicis tenosynovitis; (*c*) middle-finger tenosynovitis; (*d*) spread from a pulp abscess of the thumb, possibly by the lymphatics.

Diagnosis.—The sign described by Kanavel, which he calls "ballooning of the thenar eminence," is very characteristic of the condition seen.

(C) *Lumbrical spaces.*—These became infected in two ways: (*a*) as a complication of tendon-sheath suppuration; (*b*) as an extension from an abscess under the horny skin of the palm. Abscesses in this situation spread to the dorsum of the web and usually healed readily on being freely drained in the manner previously indicated.

(D) *Abscess in the forearm.*—This can arise in two ways: (*a*) by rupture of a palmar bursa suppuration (first or fifth finger tenosynovitis at the upper end, above the annular ligament); (*b*) by spread of a middle palmar space abscess deep to the flexor tendons. In each case the same space in the forearm is affected, a space limited above by the attachment of the flexor profundus digitorum to the ulna. The abscess points at the ulnar side of the forearm about its middle, and it is here that it should be opened.

Fascial space abscess is later in its ætiology than its two companions in Group II. It is to be regarded rather as a complication of tendon-sheath suppuration than as a complication of the three early conditions in Group I.

Carbuncular and Trivial Infections; Lymphangitis and Glandular Abscess.

Carbuncular infections occurred only on the dorsum of the hand or fingers where hair follicles were present. They appeared to do as well when treated by fomentations and a stock staphylococcal vaccine as they did when incised. Excision left a wound which took long to heal.

There were 28 cases of trivial infections, of which 26 were subcuticular abscesses. No anæsthetic was required unless a deeper infection was present as well. The covering dead cuticle should be entirely removed; if this is done healing should not occupy more than a few days.

Lymphangitis and glandular abscesses were far more common where the primary focus was situated on the dorsum of the hand or fingers. Cases of lymphangitis generally resolve when the primary focus is treated, and the same is true of enlarged glands; but when there is is evidence of suppuration adequate incision must be made.

The established treatment of cellulitis by multiple incisions is not altogether satisfactory. In cases where pus is evacuated by this means the results are good, but it is in the severe cases where only brawny œdematous areas are exposed that the results of incision are least satisfactory. It seems to be better treatment to place the part at rest and apply fomentations until it localises into one or more abscesses, which are then opened in the most dependent position.

Conclusions.

The analysis of the 168 cases which form the basis of this paper shows that hand infections as seen in working men and women are too frequently the cause of grave disability. It was very unusual for a case to develop a severe infection if it had been first seen whilst it was in the Group I. stage.

Part of the blame must be attributed to the prevalent impression in the minds of the lay public—and it is to be feared in the minds of some members of the medical profession—that a "whitlow" is a suitable object for treatment with poultices, ink, ointment—in fact, anything but free drainage. The time to treat these conditions efficiently is in their early stages. When tendon sheaths, &c., have become infected the hope of a useful finger is a thing of the past; the object of treatment then becomes to save whole hands, forearms, and even lives.

The outlook of the public and the profession towards hands is much the same as it was towards the appendix 20 years ago. If localised tenderness became the danger-signal in the hand, as it has become in the abdomen, and if suppuration in the hand, however small the area involved, were regarded as an indication for immediate operation the morbidity of infected hands would fall in much the same way as the mortality of infected appendices has fallen.

Several factors combine to retard progress in this form of industrial disease. Not least amongst these is the fact that the public and the politician are each obsessed with the idea that all diseases can be treated with something out of a bottle. So we have elaborate schemes of State insurance, which do not consider the fact that the general practitioner can have neither the time nor the facilities, such as anæsthetics, for treating many of these cases.

I wish to thank the surgeons to out-patients of the London Hospital for permission to see and make use of their cases, and particularly Mr. A. J. Walton for valued suggestions and advice.

It would be impossible to write on infected hands without trespassing on Kanavel's work; my excuse for having done so is that his book is only obtainable from America. In two items only can I make any claim to originality: (1) The view of palmar abscess as the commonest cause of tenosynovitis; (2) the method of securing the proximal end of the tendon to the proximal phalanx before excising it.

DUBLIN UNIVERSITY BIOLOGICAL ASSOCIATION: ANNUAL DINNER.—The annual dinner of the Dublin University Biological Association—in suspense since 1914—was held last week in the Gresham Hotel under the presidency of Dr. Bethel Solomons. Over 100 members attended, and a very pleasant evening was passed. The principal guests present were the President of the Royal College of Physicians, Major-General J. J. Gerrard, and Sir John Lumsden.

SPECIFICITY AND EVOLUTION IN DISEASE

A HISTORICAL RETROSPECT.

BY SIR WILLIAM JOB COLLINS, K C.V.O , M.S ,
M D , B SC LOND , F.R C S ENG.

THE LANCET of May 14th, 1881, published a letter in which I ventured to inquire "how far our commonly accepted notions of specificity of diseases should be modified by the doctrine of evolution " I then said.—

> "This *doctrine, which has so rapidly and entirely altered the face of the organic world,* as we conceive it has as yet made but a feeble impression, if any, on medical science and pathology The importance of the principle of specificity in disease has been clearly and generally recognised since the time of Laennec and Bretonneau Trousseau in one of his clinics devoted to the subject, remarks of specificity Elle domine toute la pathologie, toute la thérapeutique, en un mot toute la médecine and the same belief, tacit or avowed would seem to pervade all modern medical literature '

I then went on to show that the argument upon which medical writers based their theory of specificity of disease was an appeal to the analogy alleged to exist between the natural history of diseases and the natural history of animals and plants, and that until that time no better argument had been possible I then inquired whether—

> "Since, as regards the organic world, we have come to speak of an origin of species, and learnt to trace their differentiation under the influence of evolution to the eventual survival of the fittest, *should not our views concerning specificity of diseases* undergo a similar *modification? Is not the theory of specificity* swallowed up in the larger theory of evolution? Starting from a non specific inflammation or fever, may there not arise therefrom under favourable conditions an inflammation or a fever different from the parent stock and capable of reproducing itself? I think so, ' and the letter concluded, "The common ancestry of specific diseases, once recognised, would do much to remove the hard and fast line so often drawn between disease and disease in text books and dissertations, but of which nature knows nothing '

On Feb 28th, 1884, I developed the thesis more fully in an address delivered at the Abernethian Society of St. Bartholomew's Hospital. This address was subsequently published by Messrs. H. K. Lewis, and was entitled, "Specificity and Evolution in Disease." Mr. Herbert Spencer was so good as to accept its dedication to himself, and wrote that "its conception is thoroughly philosophical and promises to open the way to a considerable reform in pathology." In this essay an attempt was made to show how pathology had been hitherto uninfluenced by evolution; the creed and canons of specificity were examined, and damaging admissions cited; the specificising influence of soil and predisposition were dwelt on, and the de novo origin of disease, variation, hybrids, and nondescripts discussed; the germ theory was viewed in the light of evolution, and certain objections on behalf of bacteriological pan spermists were rebutted. The argument was thus summarised:—

> "Starting from *common ancestral conditions*, we arrive at *specific diversities*, and that the chief, if not the only, element in determining specificity is the *nature of the soil*, in which the poison (whatever be its nature) grows, that is to say the *predisposition of the individual* That the predisposition varies with the departure from a state of health, local or constitutional, but that just as in some cases so great is the virulence of the poison *as the result of cultivation on suitable soil*, that it may even overstep the usually sufficient barriers of health and attack the unpredisposed so, on the other hand, predisposing and exciting causes being as it were, complementary, predisposition may be so strong that, apart from contagion, it may develop disease *de novo* Such disease, however, as with *nascent species* generally, being more plastic, *less fixed* than the *more cultured* variety, *and often appearing in aberrant form* "

The same principle, it was suggested, might be applied to local inflammations.

> "The evolution of specific local lesions from the different stages of a common or simple inflammation, as, for instance, the various classes of skin diseases, erythemata, papulæ, vesiculæ, pustulæ, and squamæ, from the stages of redness, pimple, blister, pock, and scab of inflammation, and likewise the ætiology of carcinoma, sarcoma, and the specific lesions of syphilis &c, from ancestral common types ' *The essay closed on a* therapeutic or hygienic note claiming that ' filthy *conditions and the imperfect removal of effete material,* without and within the body, are the *factors of* zymotic pestilence, which aforetime walked in darkness, but is now made plain by the revealing light of science And just as the evolution theory of disease asserts the origin of disease so does it foresee the possibility of its abolition, at any rate so far as zymotics are concerned, while *it was an integral part of the old specific theory to affirm that* disease was from everlasting to everlasting, as it was in the beginning it is now and ever shall be, and that salvation could only be purchased by the propitiating influence of a previous attack

This was in harmony with the plea for "extended sanitation, for the means of fighting diseases outside our bodies and not within them, for making our hygiene so good that prophylactics and antiseptics shall be superfluous," which I had argued in THE LANCET of Nov. 16th, 1880

My innocent enthusiasm for evolutionary pathology as a corrective of the rigid doctrine of specificity, however, came under severe censure from the reviewers. The *London Medical Record* (August 15th, 1884) declared —

> Such teaching runs counter to all the best work of modern times, which has carefully distinguished many of these forms of disease from one another or from others with which they were confounded

The *Medical Press* (May 14th, 1884) accused me of—

> "essaying with all the vigour of youth to demolish the theories of specific disease which have sufficed to satisfy the acutest physicians of this and every age and discovered in the essay a ' proneness to jump over those *terrible* gaps *which* everywhere occur to separate the known *from* the unknown

While saying many kind things, which I forbear to quote, the reviewer regrets to find—

> ' evidence of generalisations which when the author has reached the experience of the authorities whose opinion he condemns, he will be less eager to adopt '

Impenitent and unabashed by this orthodox rebuke from pontifical seniority, I again raised the question of "specificity and evolution in disease" at a conference of medical officers of health held in the Guildhall, Worcester, on Sept 26th, 1889.[1] Wallace's "Darwinism" had just been published, and alluding to it I remarked —

> "It has been the work of Charles Darwin and of Alfred Russell Wallace to alter the face of organic nature as we conceive it and to give us truer and finer conceptions alike in ontology and biology *It is the object of this paper to inquire as I inquired eight years ago, Has the science of medicine,* as we are *pleased to term it,* reaped the full benefit of these new conceptions? A small and increasing number of philosophic pathologists has doubtless essayed to bring the quickening influence of evolution to bear upon the dry facts which for centuries have been accumulated with such an infinity of labour and prolixity and such a modicum of insight and synthetic thought We have but to take up any *ordinary text-book of medicine to find that such underlying* scientific conceptions as it may happen to include are but a dim *reflex of the fossilised* biological *notions* which did duty *before* Darwin's day The old, absolute, unalterable and eternal specificity theory is there in all its crude inconceivability and its theological attire '

The alternative evolutionary thesis was then re stated, the predominant position of the germ hypothesis as affording an obstacle to the acceptance thereof, and the basis of orthodox criticism of evolutionary pathology were examined.

> "Micro-organisms, it was contended, "have come to be regarded too much in the light of their relation *to diseases of* man and *too little in the light of their own life-history the old* notion *of a specific organism or entity* as the *vera causa* of disease *commends itself to acceptance if* only on the score of its simplicity and easy comprehensibility The *raison d'être* of fission fungi in the minds of some pan-spermists would appear to be the infliction on mortals of exanthematic disease, for such purpose they hold they are and were created Whereas I apprehend the truer view to be that it is just *so far as living* tissues under certain conditions afford *suitable soil for their growth and multiplication* that there is *any relationship* between the two, and it is *only by the results of* their presence and growth, facilitated by the *means of* absorption and distribution which the mechanism of the living body provides that they come to be really pathogenic In cases where a micro-organism is habitually present it may be *questioned* whether its pathogenic *modus operandi* may not be merely to facilitate a chemical change which *may* be effected without it as we know may *occur in normal digestive processes* '

It was submitted that the facts related

> "do not warrant our *insisting* that the acceptance within limits *of* the *bacterial* hypothesis *for* certain diseases implies a strict acquiescence in the truth of a rigid specificity the dissemination of fission fungi may be rather epiphenomenal than of the nature of a predestinated cause Again, since what may stand as a specific series of morbid phenomena may be determined by a chemical poison in which the bacilli which produced it are conspicuous *by their absence how far is their* presence to be held a *proximate* cause in disease production? Lastly, *inasmuch as soil may operate* to the extent of nullification *of the action of a bacillus* which is uniformly fatal to another variety of the same species of animal how great is the importance to be attributed to it as a factor in the propagation and modification of disease' It is impossible at the present time to go further than to allow that the influence which makes for disease is in some instances associated with the growth *of fission fungi in the body*.

> How vast and incomprehensible may be the potentiality vested in a minute morphological unit we know in the phenomena which follow the inter-action of ovum and spermatozoon; of the intimate nature of contagion we know but little more. Yet if it be true that in the life-history of the lowest of organic things lie the momentous influences which determine plagues and pestilences, it is reasonable to believe that in organisms whose cycle may be less than an hour, and whose rate of propagation is incalculable, evolution must be powerfully at work eventuating in the survival of those most fitted to their environment, and that in this as in other directions man's influence may modify natural selection, and by acting in accordance with law learn to conquer nature by submitting to her."

In the debate which followed Mr. Blyth, Dr. Bond, and Dr. Sykes had very complimentary things to say; the first-named, however, thought "the subject could be more profitably discussed in some 20 years hence than at the present time," the last-named remarked that "if Dr. Collins had done nothing more than to teach them they must not lay down any hard-and-fast rules he had done some good," while Dr. Bond dwelt on the "plasticity of the germ," and added that:

> "The general result of his observations had been to lead him so strongly in the direction of what Dr. Collins had shadowed forth that he felt he had travelled altogether from the original ideas as to specificity which he entertained when he first undertook the work of a medical officer."

Dr. (now Sir Arthur) Newsholme wrote to *Public Health*[2] saying he had—

> "read with great interest Dr. Collins's paper. It is an able exposition of the evolutionary view of the origin of febrile disease from an ancestral amœboid common fever, and puts in a lucid manner the arguments favouring this theory." Nevertheless, he added: "Carefully conducted and elaborate experiments in the bacteriological laboratory, made by quite a small army of observers, tend to throw great doubt on the present transition of any one known species of bacteria into any other. ...... It must be confessed that however much one may be theoretically inclined to agree with Dr. Collins's evolutionary views respecting infectious diseases, and in spite of the fact that he has presented his case in a very masterly fashion, the evidence hitherto available negatives the view that modification of form occurs, and leads one to think that it is chiefly and to all appearances solely a question of modification of soil."

At intervals during the 30 or 40 years which have elapsed since I first hazarded views that gave rise to such diversity of opinion I have, in the intervals of other activities, returned from time to time to this fascinating theme. Among such re-statements of the case were addresses at King's College, Feb. 14th, 1896, entitled, "Pasteur Notwithstanding"; at the Sanitary Institute Congress at Manchester, in 1902, in "the popular lecture" entitled, "The Man versus the Microbe[3]; in a lecture to the Abernethian Society on "Physic and Metaphysic," Feb. 16th, 1905[4]; in the presidential introduction to the Section of Preventive Medicine at the Sanitary Congress at Bristol in 1906[5]; in an oration to the Reading Medical Society in 1909 on "The Tithing of Mint and Anise"; and in the lecture to the Congress of the Sanitary Institute at Exeter in 1913 entitled, "The Chadwick School of Thought, an appeal from the New Sanitarians to the Old."[6] I therein urged that accumulating evidence strengthened rather than weakened the original claims made on behalf of evolutionary pathology. In 1888 and 1904 letters entitled, "In What Does Cancer Consist"[7] and "Herbert Spencer and Evolutionary Pathology"[8] collateral topics were dealt with. Confirmation of the views which were accounted so preposterous and heretical by the early reviewers, sometimes unacknowledged[9] and sometimes acknowledged, has been abundantly forthcoming during the generation which has since elapsed. Thus Dr. T. W. Thompson, writing on "The Natural History of Infectious Diseases,"[10] referred to my essays of 1884 and 1889 and asserted that—

> "Evolution in connexion with epidemic diseases, or more strictly their causes, is day by day forcing itself more prominently upon our consideration."

Dr. K. W. Millican, an early worker in the same field, wrote on "The Evolution of Morbid Germs."[11] Dr. (now Sir George) Newman, in 1904, in his work on Bacteriology,[12] spoke of the tendency to overrate altogether the potentiality of the bacillus apart from its medium, and of "the enormous part played by the medium or soil in which the micro-organism is growing." In sending me a copy of his book he said—

> "I have tried to learn the lesson you used to emphasise—the relativity of bacteriology and its tentativeness. I have also used your ideas of seed and soil in Chapter I."

Dr. J. T. C. Nash, medical officer for the county of Norfolk and formerly of Southend, has from 1901 onwards emphasised and illustrated with great cogency "the part played by evolutionary forces in disease processes."[13] Dr. W. H. Hamer, medical officer to the London County Council, in his Milroy Lectures before the Royal College of Physicians of London, in 1906,[14] as well as in his brilliant annual reports, dwells on "the paramount importance of soil" upon specificity, and cites with approval my observation that "the possibilities of environment are not exhausted by the confectionery of the laboratory." In 1902 Dr. Howship Dickinson[15] and Dr. Stephen Mackenzie,[16] in addresses at St. George's Hospital and at the Medical Society, stressed the importance of paying more attention to the soil than to the seed in diseases attributed to microbic causes. In a critical annotation in the *Universal Medical Record* on "The Pathogenicity and Virulence of Bacteria,"[17] reference is made to the researches of Dr. F. H. Thiele and Dr. D. Embleton,[18] which it was alleged, if substantially confirmed, would cause the whole of the enormous superstructure that has been reared on the basis of the conventional bacteriology of the last 20 years or so to go by the board. The writer continues:—

> "Views, although supported by clinical observation, which have been held heterodox, may now be brought out into the light of the day, and the importance of the man in respect of the microbe may perhaps be freely acknowledged."

and the Manchester address on "The Man versus the Microbe" of 1912 is cited in support of this contention. Sir Malcolm Morris,[19] in his introductory volume to Cassell's series of Public Health Manuals, says:—

> "In the early days of bacteriology some sanitarians were slow to appreciate the rôle of pathogenic organisms. More recently the pendulum has sometimes swung too far to the other side, and Sir William Collins is not without justification for the epigrammatic warnings he has administered from time to time against the danger of underrating 'the potency of filth and removable conditions as factors in disease production and propagation.'"

In 1918 Professor J. G. Adami[20] published his "Medical Contributions to the Study of Evolution," recording views he had arrived at in orderly sequence from the year 1891, and maintained that—

> "In studying these uni-cellular a-sexual bacteria, we investigate the simplest and most fundamental principles of heredity and evolution, and the influence of environment becomes most evident," and "that to a variability which may impress itself upon a greater or less number of generations is to be ascribed, in part, the differences between successive epidemics, between the successive stages of one epidemic, and between individual cases of disease."

Last year Dr. Gurney Dixon[21] published a work entitled "The Transmutation of Bacteria," and, after a full review of recent literature on the subject, concludes that—

> "There is no reason to doubt and abundant evidence to support the opinion that in this field of life, as in others, the forces of natural selection and the survival of the fittest have been at work and have resulted, in the course of ages, in the evolution and differentiation of the various types of bacteria which we recognise and distinguish to-day," and again, "it is reasonable to expect that amongst the bacteria natural variation would occur with greater frequency than amongst higher forms of life. . . . Such variations would be more readily noted in their case since as many as 30 or 40 successive generations may be observed in the course of 24 hours."

The author points out that—

> "No single property of bacteria can be regarded as specific," and that the pathogenesis attributed to an organism may be dissociated from it; again he says: "Species of bacteria have developed from a common stock. In the case of some of them the differentiation dates from a remote past and the specific characters are comparatively fixed. In the case of others differentiation is of more recent date, and the newly-acquired characters are less permanent and 'reversion' in one or other character is more frequent."

Dr. F. G. Crookshank,[22] who in earlier writings as well as in his Chadwick lectures had shown a scholarly and philosophic method of investigation into the fundamentals of pathology, was able to read, without other than appreciative criticism, to the Section of Epidemiology of the Royal Society of Medicine on Jan. 23rd, 1920, a paper on "First Principles: and Epidemiology," which was instinct with the doctrine of evolutionary pathology. Fortified with illustrations drawn alike from the laboratory and the library, he challenged physic to listen to metaphysic and to condescend to define its terms and prove its propositions. He asserts that

"The attempt at recognition of epidemiological *principles* seems, indeed, during the nineteenth century, to have been almost abandoned Statistics and field-observations are matters of *method, not of principle*, and for the rest, the *cathedra* of the professed epidemiologists seems to have wobbled uncertainly on two legs one the dogma that specific diseases were real things to be found in the post mortem room' the other that epidemics were to be abolished by sanitation Both beliefs were bred by *a posteriori* methods out of Victorian realism Within our own memory an attempt has been made to secure equilibrium by the insertion of a third support that of systematic bacteriology Almost alone, Sir William Collins some years ago raised his voice against the positivist doctrines of specificity in disease, and the excessive claims of the bacteriologists Now that the inflated claims put forward in some quarters have collapsed his papers may be studied anew

May I, having now briefly reviewed my reviewers, with due submission, repeat the question I propounded 40 years ago in your columns "Is not the theory of specificity of disease swallowed up in the larger theory of evolution?"

A CASE OF

GASTRO-COLIC FISTULA

BY DOUGLAS FIRTH, M D. CANTAB, F.R C P LOND,
JUNIOR PHYSICIAN, KING'S COLLEGE HOSPITAL

AMONGST the rarer complications of gastric ulcer is numbered gastro colic fistula, and whilst it is recorded in most text books of medicine, no mention is made of the possible means of diagnosis. This is to be regretted, for though gastro colic fistula is undoubtedly rare, it should prove easy to diagnose.

Fistulæ between the upper and lower part of the alimentary canal in the abdominal cavity fall into two groups · the one in which the fistula arises spontaneously, the other in which it follows the operation of gastro enterostomy, and is more frequently jejuno colic than gastro colic Of this latter variety Dr. Charles Bolton has had a comparatively large experience, no fewer than 31 cases, and, as he pointed out at a recent meeting of the Royal Society of Medicine, when the communication between the stomach and colon is indirect—that is, via the jejunum—the diagnosis may be extremely difficult In all his cases, however, a history of operation for gastric ulcer was present, which to those cognisant of the possibility of an intestinal fistula, serves as a valuable clue to originate an investigation to elucidate the condition. In the case here recorded a correct diagnosis was not made The past history was indefinite, the patient had undergone no operation, and two of the most characteristic symptoms, diarrhœa and vomiting, subsided on admission to hospital, so that no opportunity occurred to investigate their nature. Nevertheless, such features as the case presented should have raised suspicions, and these once aroused, it would have been easy to prove or disprove the presence of a gastro colic fistula.

The patient, a male aged 51 years, was admitted to hospital for diarrhœa and vomiting at irregular intervals, pain in the chest, and a "swollen stomach" The attacks of diarrhœa and vomiting had commenced in February, 1919 and usually were in evidence together, but sometimes when vomiting was present alone the onset of diarrhœa stopped it The length of the bouts varied much, and they were not accompanied by pain. Wasting had commenced at about the same date, the fall in weight being from about 11½ st to 9 st 6 lb on admission to hospital The pain in the chest was not particularly severe, and was stated to be at a maximum before food and to be relieved by a meal "Flatulence" had been a marked feature, and the peculiarly *offensive character of the eructations* was noted in the out *patient department before admission There was no history of hæmatemesis, melæna, or anything suggestive of gastric* ulcer, and with the *exception of an attack of jaundice at the* age of 23, the patient alleged that he had been *a healthy man* until the onset of the present illness

On admission the patient was emaciated, with a sallow complexion, offensive breath, and dirty tongue The abdomen was full, contrasting markedly with the wasted condition of the man, but there was no tenderness on palpation and no mass or other abnormality could be detected All the other systems were normal On the fifth day after admission slight but definite ladder pattern peristalsis was seen on examining the abdomen, and on the following day a brief attack of vomiting occurred, during which no peculiarity in the vomit was noted The bowels throughout acted regularly without an aperient

A week after admission an exploratory laparotomy was performed, at which distension of some of the loops of the small intestine was found, and a large adhesion stretching from the cæcum to the omentum, was divided Following the operation the patient gradually sank, dying 14 days after without apparent cause, *there had been no return of the diarrhœa and sickness, although the abdominal distension continued in spite of the regular action of the* bowels

Post mortem the stomach was thick walled, contained some fæcal material, and the mucous membrane showed chronic gastritis On the lesser curvature of the stomach 3 inches from the œsophageal opening, was an old chronic ulcer, which had perforated into the transverse colon, forming a large gastro colic fistula, which would admit three fingers There was perfect firm union between the edges of the stomach and colon, which was not adherent to the stomach except at this point

Remarks

A consideration of the case and of the post mortem *finding suggests that a combination of some of the following symptoms should arouse a suspicion of the* existence of a gastro colic fistula —

1 Wasting, of some duration and for which no obvious cause is present
2 Abdominal pain or discomfort of a vague type
3 Abdominal distension. This probably results from fermentation due to the regurgitation of fæcal matter into the stomach, leading to a chronic gastro enteritis
4 Offensive or fæcal smelling eructations
5 Intermittent diarrhœa, *during which the examination of the dejecta may show the presence of undigested food*
6 *Vomiting of fæcal material at intervals, without evidence of intestinal obstruction*

Confirmation of the diagnosis may be obtained by—

7 A loss of fluid on gastric lavage, a similar phenomenon to that seen in some cases of hour glass stomach
8 Recovery of material demonstrably fæcal by lavage
9 The rapid appearance of a coloured meal in the stools, charcoal would answer the purpose excellently
10 The recovery, from the stomach, of colouring matter administered as a rectal enema
11 A bismuth meal In jejuno colic fistula, the picture presented by an X ray examination may be confusing, owing to the numerous routes open for the bismuth to travel, but where the fistula is solely *gastro-colic, the findings should* be much more definite

The existence of a gastro colic fistula should also be suspected if there is a history pointing to or suggesting a previous gastric ulcer, although such a history, as this case shows, is not invariable.

THE Bristol County Sports Club has collected £1000 as a Thanksgiving War Memorial Fund to endow a bed at the Bristol General Hospital The balance will be given to the Bristol Royal Infirmary

A MEDICAL CENTENARIAN.—Dr. James Scarth Spence Logie, of Kirkwall, Orkney, celebrated his centenary on May 11th. A member of a family well known in Orkney for three generations, he qualified L R C S Edin in 1841 and M.D. Edin in the following year, and was for long the leading physician in the islands

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

CONJOINT MEETING OF SECTION OF OBSTETRICS AND GYNÆCOLOGY WITH NORTH OF ENGLAND AND MIDLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETIES.

A CONJOINT meeting of the Section of Obstetrics and Gynæcology with the North of England and Midland Obstetrical and Gynæcological Societies was held on May 6th.

MORNING SESSION.

Dr. J. E. GEMMELL (Liverpool) presided.

Dr. E. HASTINGS TWEEDY opened a discussion on

The Treatment of Ante-partum Hæmorrhage.

He said that comparison of results in accidental hæmorrhage was difficult because in the compilation of different statistics different standards were adopted. The classification as accidental hæmorrhage of all antepartum hæmorrhages other than those arising from placenta prævia was a mistake commonly made by nurses and students. Of still greater importance was the determination of the amount of loss which brought the condition within the category of accidental hæmorrhage. In the Rotunda Hospital the term was not now used unless the bleeding was sufficient to necessitate calling an assistant master to make a diagnosis and to be responsible for the woman's delivery. He was not summoned unless his presence was required in the interest of the patient, and in this way many insignificant bleedings escaped the records. Thus during his mastership of the Rotunda Dr. Tweedy reported only 49 cases of accidental and 45 of unavoidable hæmorrhage in 13,924 deliveries, and in the extern maternity 47 in 15,543 deliveries. On the other hand, Sir William Smyly, adopting a different standard, in his first hospital report on 3600 deliveries, recorded 44 cases, of which he wrote, "Most of them were of little consequence." Similarly, at St. Mary's Hospital, Manchester, 105 cases of accidental hæmorrhage were encountered in the two years 1913-14; 83 of these recovered under the measures applicable for the condition in its less severe form (rupture of membranes, and so forth). Seven died in spite of this treatment and 15 were dealt with by more radical procedures. From these figures Dr. Tweedy inferred that there were certainly 22 serious hæmorrhages, but that the remainder could probably be classed with most of Sir William Smyly's cases as "of little consequence." Amongst Dr. Tweedy's 49 patients 22 were in serious danger and were treated by the vaginal plug. He lost 2 hospital and 7 extern maternity patients, in 5 of whom the plug was employed. His two hospital deaths probably arose from intraperitoneal hæmorrhage, for in one not more than a pint and a half of blood poured into the uterus, whilst in the other the patient's condition improved whilst the plug was in, and the patient died only after completion of the third stage three hours after. From 1913 to 1918, during which time Dr. Tweedy was back at the Rotunda, 23 cases of accidental hæmorrhage were encountered. The possibility of accidental hæmorrhage arising as a result of pregnancy toxæmias had by then been established and led to the performance of Cæsarean section when the double complication was encountered in a severe form. The procedure was carried out three times with success. Intra-abdominal blood was observed in all three cases, and in one the ovarian artery beneath the Fallopian tube was bleeding. Of the remaining cases, 8 were plugged. No deaths occurred from loss of blood. One woman died from sepsis ten days after delivery. Thus Dr. Tweedy's hospital experience comprised 72 cases in over 18,000 deliveries with 2 deaths. Thirty were plugged. Sir William Smyly, working in the same institution, had 5 deaths in 3600 patients treated before his adoption of the plug. These figures were convincing, and could only be explained on the assumption that the plug exercised a pronounced influence on hæmorrhage. It acted by impeding the circulation in the uterine vessels. Various other more or less satisfactory explanations had been given of the plug's action. Berkeley and Bonney had satisfied themselves that the efficacy of the plug depended on its increasing the power of the uterus to contract. In dealing with concealed accidental hæmorrhage, however, with the accompanying uterine inertia, they were driven to express a doubt whether the plug could have any directly useful effect. A plug applied in the method recommended by these writers would not compress the vessels, for they applied it with the aid of a speculum and a forceps, and used rolls of cotton, each tied round with a string to facilitate removal. Dr. Tweedy felt sure it would not be possible to place in position one dozen such rolls as are portrayed in their illustration, and that those adopting any similar technique must meet with disappointment. He had quoted from Berkeley and Bonney, not because they were singular in their views, but because of their great eminence. They undoubtedly voiced the popular opinion that it was useless to attempt the compression of blood-vessels by a vaginal plug. However, Dr. Tweedy maintained that compression was accomplished with the plug which he applied, and he had demonstrated this during the performance of several Cæsarean sections. These operations had afforded his assistants an opportunity of directly observing stoppage of pulsation in the uterine artery whilst pressure was made from below. Dr. Tweedy then described his method of plugging as follows:—

> To plug efficiently the left hand should be passed into the vagina with the palmar surface directed towards the hollow of the sacrum, while the tip of the fingers lie behind the cervix. Small pieces of cotton-wool, squeezed out of lysol solution, and each of the size of the thumb-knuckle, are then taken and inserted, by means of the right hand, round the cervix. The fingers of the left hand are kept busy squeezing the pellets into a compact mass, and forcing the spaces between them to permit the insertion of still another plug. This process is continued in a systematic manner from above downwards till the vulva is reached, and the vagina can hold no more. A T-bandage is applied to keep the plug in position, and an abdominal binder is fastened tightly from above downwards to press the side walls of the uterus against the vaginal dam, and thus completes the operation. A plug so applied will cause immediate cessation of hæmorrhage, and when it is removed after the lapse of hours so much blood only will be found as can be accounted for by the flow that took place during the operation.

The vaginal plug was not easy to apply, nor was its application harmless. If at the first attempt sufficient material could not be inserted to stop the bleeding, the plug had to be removed entirely and reinserted, a procedure made easier by the dilatation of the vagina. Pain, distress, and some shock always followed the application of the plug, and superficial tearing of the mucous membrane of the vagina was almost certain to occur, whilst the possibility of rupture of the uterus could not be discounted. It was clear that the words "vaginal plug" mean in Dublin something different from that which they meant elsewhere, and critics must take this into consideration. To what extent intraperitoneal hæmorrhage could be controlled by a vaginal plug was still a matter of doubt. In the vicinity of the internal os control was complete. On the other hand, it would utterly fail to stop a leakage from the ovarian artery. The latter supplied a relatively small amount of blood to the placenta, chiefly to its upper portion where detachment was rare. When the main supply was cut off the loss of blood pressure promoted coagulation in the sinuses.

Dr. Tweedy maintained that hysterectomy had no place in the treatment of accidental hæmorrhage. Finally, he stated that rupture of the membranes did not contra-indicate the vaginal plug.

Discussion.

The PRESIDENT said that the difficulty in treating ante-partum hæmorrhage, both of the accidental and inevitable type, was to apply the surgical axiom "put one's finger upon the bleeding spot." Still, there were means towards this end, and he thought that plugging the vagina by the Dublin method would certainly relieve the urgent symptoms for a time. In placenta prævia he thought that the associated uterine inertia was a very important factor to combat. Cases of ante-partum hæmorrhage would be divided into two very important groups. The first included all the cases where there was a mere trickle of blood, by far the greater proportion. These usually recovered with rest and morphine, and it was not necessary to interfere further. The second group included the severe types of bleeding where plugging might be employed with advantage. Unfortunately efficient plugging was very difficult, and few practitioners could do it properly.

Dr. FLETCHER SHAW (Manchester) congratulated Dr. Tweedy upon his results. He was also very glad that he had raised the question of diagnosis. He was of opinion that many cases recorded as accidental hæmorrhage were really marginal placenta prævia. In Manchester the routine treatment in these cases of accidental bleeding was to rupture the membranes, put on a binder, and give ergot, and he thought that the results were equal to those obtained by the use of the vaginal plug. One grave objection to plugging was the attitude of the general practitioner. Hæmorrhage was a very alarming symptom to the practitioner, and when confronted therewith he employed that method which he was taught as a student to be safe. If plugging was regarded as the method of election cases would inevitably arise where septic material was used for the plug, and this would add another risk to the patient. Calamities did in fact occur to-day from this very cause. For this reason he favoured the less risky method which he had mentioned. On the question of hysterectomy in cases of severe accidental hæmorrhage of toxæmic origin, he thought that this would seldom be required. Before 1916 he had met with six such cases, but none since then. As to unavoidable hæmorrhage, he agreed with the view that Cæsarean section should be used much more frequently when the child was alive.

Dr. HERBERT WILLIAMSON (London) submitted the results of treatment of accidental hæmorrhage at St. Bartholomew's Hospital since 1911. 2600 patients had been admitted to the maternity department, and amongst these were 98 cases, or 3·67 per cent., of ante-partum hæmorrhage. Fifty of these were true accidental bleeding and 48 were cases of placenta prævia. Of the former, 47 mothers recovered and 3 died. Twenty-seven of the children were born alive and 23 dead, a mortality of 46 per cent. Of the cases of placenta prævia, 12 were central, 27 lateral, and 9 marginal. Forty-five of the mothers recovered, the mortality being 6·25 per cent. Amongst the children, however, there were 32 stillbirths—i.e., a fœtal mortality of 66·6 per cent. As regards treatment, no local interference at all had been necessary in 58 per cent. of the cases of accidental hæmorrhage and in 16·6 per cent. of placenta prævia. Rest, position, and morphine had sufficed. Of the remaining cases, bipolar version had been performed eleven times, dilatation of the cervix three times, De Ribes's bag 18 times, Cæsarean section three times, and once for placenta prævia. Whenever vaginal plugging was required it was always done under a general anæsthetic, and strips of gauze were employed. The speaker had divided these cases into the following four groups: Group I., bleeding arrested and no further treatment required, 8. Group II., bleeding arrested but labour-pains not instituted, 3. Group III., bleeding recurred in three hours, 3. Group IV., bleeding not arrested by the plug, 4. In these 18 cases where plugging had been used there had been two maternal deaths. Of the children 5 were stillborn. Dr. Williamson, as a result of this investigation, had come to the following conclusions: Firstly, that the vaginal plug is a valuable method of treatment, and that in the majority of cases hæmorrhage tends to be arrested by its proper use. At the same time, it is not infallible, and whoever employs it must be prepared to go on to other measures. Secondly, that in the toxæmic variety of accidental hæmorrhage Cæsarean section is the only treatment. The speaker was not prepared to accept Dr. Hastings Tweedy's explanation of how the vaginal plug controls bleeding in these cases. He did not believe that it compresses the uterine vessels, and, even if it does, the anastomosis of vessels is so free that he thought it would be impossible to cut off the blood-supply to the uterus by this means.

Dr. HERBERT SPENCER (London) thought that the meeting was to be congratulated in having Dr. Hastings Tweedy's experience laid before it, and he was very interested in the results that he had brought forward. At the same time he wished to point out that, after all, many of these so-called cases of ante-partum hæmorrhage were of very little importance indeed. Anyone with much experience must know that it is rare indeed for Cæsarean section to be required for placenta prævia. Dr. Spencer had had a very large experience—in fact, it dated from last century, and he had only thought Cæsarean section necessary upon two occasions. One of these cases was where the child was alive and the cervix undilated, the other was the complication of placenta prævia with twins and hydramnios. He was led to condemn the general employment of the Cæsarean operation for placenta prævia in the strongest terms. As regards the treatment of accidental hæmorrhage, plugging had given very good results in his hands. He was glad to hear that Hastings Tweedy had condemned hysterectomy for this condition. Cæsarean section might be required, but hysterectomy never.

Dr. BLAIR BELL (Liverpool) thanked Dr. Tweedy for his very lucid explanation of the use of the vaginal plug. He was convinced that it was a valuable asset to treatment, but he could not agree with the action attributed to it. He thought that it was physically impossible to control the uterine arteries by this means, and even if the arteries were tied he did not think that the bleeding would be controlled. The more usual explanation that the plug stimulated uterine contractions was the probable one. The question was important, and he should like to see it settled by experimental investigations upon an animal such as a pregnant chimpanzee. The speaker asked for information with regard to the use of pituitrin in cases of severe accidental hæmorrhage. Personally he had not much experience of the complication, but he thought that when the membranes were ruptured it might be useful if given in moderate doses. As regards placenta prævia, he also was of opinion that there was only one treatment, and that was Cæsarean section. He had been using this treatment since 1912, and had only lost one mother and one baby.

Dr. W. E. FOTHERGILL (Manchester) referred to the teaching of students and midwives in connexion with the treatment of ante-partum hæmorrhage, and drew attention to the correspondence upon this matter which had passed between the Central Midwives Board and the examiners under the Board. He thought that it was a matter of extreme importance for teaching purposes that a definite treatment should be formulated to be used by midwives. What we thought was one thing, but equally and perhaps more important was what we taught. As regards the use of the uterine plug, he could not advise students to plug on account of the very grave risks of sepsis involved. He had seen too many absolute tragedies ever to make him an advocate of this measure.

Dr. G. W. FITZGERALD (Manchester) observed that it was evident that there were two schools of thought in connexion with the treatment of ante-partum hæmorrhage. To his mind the important factor lay in whether or not the uterus was contracting at the time of the bleeding. If the organ was active there was no need for contention, since it would do all that was required, and no active measures were indicated. The speaker said that he had had the privilege some years ago of working under Dr. Tweedy, and he was quite convinced that the old theory that a vaginal plug converted a revealed into a concealed variety of bleeding was fallacious. He was a rigid adherent of the plug, but all the same, since its use did not save the child, he thought that Cæsarean section *must* be considered. Also, in concealed accidental hæmorrhage extirpation of the uterus *might* be necessary. In cases where uterine contraction did not occur after the Cæsarean operation for this condition there was no other alternative. With regard to placenta prævia, the child must be given an equal chance with the mother, and for this reason he certainly wished to throw in his lot with those who advocated Cæsarean section for this complication. The risk to the mother was not increased, even where extreme secondary anæmia was present. This was proved over and over again in the recovery of patients following a ruptured tubal gestation.

Dr. T. W. EDEN (London) thought that it was a matter of the greatest importance that students should be taught exactly how to plug the vagina. If this were done, and the risks of sepsis thoroughly drilled into them, the dangers of the method would to a great extent disappear. The same remark applied to midwives. Under present conditions he quite agreed with what Dr. Fletcher Shaw had stated. With regard to placenta prævia, he hoped that one result of this meeting would be the formulation of definite indications for the employment of Cæsarean section in this connexion.

Dr. SYDNEY RUMBOLL (Leeds), whilst agreeing with Dr. Tweedy's indications for the use of the vaginal plug, thought that before its use the patient could be anæsthetised and every precaution taken against sepsis. Personally he had only performed Cæsarean section for placenta prævia upon one occasion.

Mr. GORDON LEY (London) said that in his opinion everything depended upon whether the uterus was active or not at the time the hæmorrhage occurred. He had discarded plugging because he had met with one case of rupture of the uterus following this method and due to necrosis of the uterine muscle. He had carried out certain pathological investigations upon this point and he felt convinced that if plugging was firmly carried out there was a real risk of necrosis. For this reason in mild cases he preferred to follow a course of inactivity. On the other hand, if the hæmorrhage was getting worse he did not hesitate to open the abdomen. In two cases he had been unable to make the uterus contract, and therefore he *had* to remove it. He had treated 120 cases of placenta prævia by external version and 61 per cent. of the babies had been born alive. He had only done the Cæsarean operation for this complication upon one occasion, and thought that it should be reserved for those cases where the patient was at or near full term, the child alive, and the cervix undilated.

Dr. R. G. MCKERRON (Aberdeen) expressed regret that Dr. Tweedy had limited his remarks to accidental hæmorrhage. He thought that this type of bleeding, although the more common, was not the more serious of the two types. He was of opinion that the plug offered the best method of treating severe external accidental hæmorrhage, and he always taught his students exact details of the technique. His experience of placenta prævia amounted to about 200 cases. In this number he had only had four maternal deaths, and he was quite in agreement with the statement that all attempts to save the child in this complication were made at the expense of the mother. The mortality attached to placenta prævia was due not to the method of treatment but to delay in its adoption. A waiting policy was too often practised. Personally he preferred version to the use of de Ribes's bag, and in the majority of cases that he had seen the cervix was sufficiently dilated to permit of bi-polar version. He had anticipated that the discussion would largely turn upon the advantages and disadvantages of Cæsarean section. He would like to point out that although this operation to-day was a safe operation, it was not absolutely safe and devoid of risk.

Professor J. M. MUNRO KERR (Glasgow) drew attention to the importance of external version in the treatment of placenta prævia as opposed to bi-polar version. The advantage of the former was that the manipulations were fewer and there was less disturbance of the placental site. Consequently, there was less hæmorrhage and a greater chance of saving the child. The great argument in favour of employing Cæsarean section in these cases was the probable lowering of the fœtal mortality-rate. He was of opinion that the fœtal mortality with the method of version existed largely because delivery is hurried. It was very wrong to hurry, and once the bleeding was controlled much more should be left to nature. In connexion with accidental hæmorrhage, he employed the vaginal plug very frequently, and agreed with Dr. Tweedy absolutely in all that he had said. He thought it very important to ascertain whether the plug really does control the uterine artery. With regard to concealed accidental hæmorrhage, he considered that Cæsarean hysterectomy *must* be performed on occasions when uterine contraction is absent. He also thought that the employment of pituitrin after rupture of the membranes was a good alternative method of plugging the vagina, and it certainly saved the patient from the risks attached to this mode of treatment.

AFTERNOON SESSION.

At the afternoon session Mr. CHRISTOPHER MARTIN (Birmingham) presided, when Mr. EARDLEY HOLLAND (London) and Professor MUNRO KERR opened a discussion on

Rupture of the Cæsarean Scar in Subsequent Pregnancy and Labour.

Mr. HOLLAND said that no accident was more disturbing to the peace of mind of an obstetric surgeon than rupture of the scar of a former Cæsarean section. His own interest in the subject had been excited by a series of five cases of rupture of the scar which had occurred in the obstetrical department of the London Hospital during the last five years. All the operations had been performed either by himself or his colleagues, and these treacherous accidents had left a profound impression. It seemed imperative to get at the true facts without delay, not only of the causes of rupture, but also as to the frequency with which ruptures occurred. It seemed all the more important because of the increased frequency with which Cæsarean section was performed and the ever-growing list of its indications. If the risk proved to be a negligible one, obstetric surgeons could with clear consciences continue to perform the operation according to its modern indications, but if the risk were appreciable safety would have to be sought either by doing fewer operations, or by devising a technique which carried less risk of rupture of the scar than the classical one. The only way to get at the truth was by obtaining the subsequent reproductive history of a large series of Cæsarean section patients; for this purpose he had invited the coöperation of many obstetric surgeons in active hospital practice throughout Great Britain, and the results of this collective investigation had been a great success, as he would show.

Mr. Holland then gave a few important points about the anatomy of the ruptured scar and the chief factors in its causation. Perfect healing of the uterine wound resulted in complete muscular regeneration; imperfect healing resulted in thin scars composed of fibrous tissue, and sometimes these scars were so thin that they consisted of little else than peritoneum and endometrium or decidua, with a little intervening fibrous tissue. The outstanding feature was complete failure of muscular union. It was, of course, these thin scars which were liable to rupture in future pregnancies. Owing to the progressive distension of the pregnant uterus the scar became thinner and thinner, and might ultimately give way under the tension of normal pregnancy or the additional stress of labour. He had collected 92 cases of ruptured scar, fully reported in the literature, and had made a close analysis of these cases, which together with his own five made a total of 97. This study had revealed that infection of the uterine wound was by far the most important factor in imperfect healing. If the uterine wound suppurated necrosis often occurred and the sutures cut out, allowing the muscular edges of the incision to retract, and ultimately leaving a thin bridge of fibrous tissue covered by peritoneum outside and endometrium inside. In the cases so far reported the recovery from the Cæsarean section had been febrile, or infection of the uterine or abdominal wounds had been noted in 51 out of 66 cases in which this point was mentioned. As regards accidental factors in rupture, a very important one was the implantation of the placenta over the scar in subsequent pregnancies. Amongst the published cases this had occurred in 33 out of 50 cases in which this point was noted. In his opinion the action of the placenta in favouring rupture lay in the occurrence of retro-placental hæmorrhage owing to separation of the placenta from the gradually stretching scar. In only

ordinary and chromic gut. His objections to the incision advocated by Professor Munro Kerr were (1) its greater difficulty; (2) its proximity to the source of sepsis.

Dr. H. S. DAVIDSON (Edinburgh) had not had a rupture, but his series did not include many cases. Silk and linen thread were used in his hospital. The decision as to the treatment of the subsequent pregnancy and the timing of the repeated Cæsarean, if performed, was very difficult.

Dr. J. D. BARRIS (London) said that the subject under discussion was a vital one. If it could be shown that the uterine scar was liable to rupture, our attitude to the classical conservative Cæsarean section would have to be profoundly modified. The cases had been collected not only for the limited period of 1912–18, but every case recorded at the hospital up to July, 1919, was included. The results were:—

Total number of Cæsarean sections (excluding sterilised cases)	81	
Number of cases treated	48—i.e.,	59%
„ „ in whom no subsequent pregnancy occurred	20 „	41%
Number of cases who subsequently became pregnant..	28 „	59%

Results of pregnancies:—

Delivery by natural passages	4
„ repeated Cæsarean section	22
„ abortion	1
Now pregnant	1
Rupture of scar	0

The method of suture employed was a buried interrupted silkworm-gut. Cæsarean section had been performed several times upon the same patient without untoward result. Dr. Barris pointed out that catgut was used in 15 of the cases of rupture collected by Dr. Holland and that sepsis occurred in about half the cases. In his opinion there was not sufficient evidence to show that the relative sterility was the result of Cæsarean section. He concluded that we were justified in performing the classical operation. Rupture was rare provided catgut was not used and that sepsis did not supervene. Should sepsis occur he suggested excision of the scar at a later date as a precautionary measure.

Dr. L. G. PHILLIPS (London) said that, excluding sterilised and fatal cases, 60 Cæsarean sections had been performed since 1912 at the Middlesex Hospital. Of these 60 cases 39 had remained sterile and 21 had subsequently become pregnant, of whom 14 had had repeated sections, 3 had had subsequent natural labours, 2 had had miscarriages, and 1 was pregnant at the present time. There had been 1 case of rupture of the scar. The interesting features of the analysis were the high sterility percentage, unexplained, and the special interest of the rupture case. With regard to the condition of the scar in repeated sections, 4 cases had had three and 11 cases had had two repeated sections, making in all 19 repeated sections. In 1 case only was the scar seen as a thin line; in the other 18 cases the scar was invisible and impalpable, and healing was apparently perfect. A most interesting feature was the anterior placental implantation in every case of repeated sections, though in the first sections the placenta was often posterior. It had been maintained that implantation on the scar was harmful, through the trophoblastic action of the placenta or the liability to retro-placental hæmorrhage. Dr. Phillips suggested that the very reverse might be true, for a thick placenta might act as an internal splint to the scar, and tend to prevent thinning of the scar region in labour. Moreover, the uterine musculature of the scar region, because of its apposition with the placenta, would not be subjected to the same muscular strain in labour as the rest of the uterus. If this were not so, uterine retractions and contractions would lead to premature separation of the placenta, which was not common. Of the 60 cases 39 had remained sterile for from two to seven years, mostly three years or over, and, excluding cases where precautions had been taken, the percentage still worked out at 52. There was no indication that pyrexia in the puerperium was a causative factor, for 68·4 per cent. of the sterile cases had an afebrile puerperium, while 27 per cent. of those subsequently pregnant had pyrexia in the puerperium. Age and parity appeared to have no influence, as half of the sterile cases were primiparæ in the twenties. The frequency of recurring pregnancies with repeated Cæsarean section indicated that the operation itself was not to blame; latent gonorrhœal infection *might* play a part. Perhaps this sterility and delayed pregnancy represented Nature's attempt to allow time for consolidation of the scar. Unless the cause could be discovered and removed, such a high sterility percentage might become a powerful factor limiting the scope of the operation.

Dr. Phillips then described the case of rupture. The patient had had very severe pyrexia in the puerperium, with suppuration of uterine and abdominal wounds, from which she nearly died. The interesting feature of the case was that the patient had been delivered naturally of a full-term child one year after the operation, and only at the second pregnancy did the scar rupture. In Dr. Phillips's opinion a natural labour should not have been allowed in a case with such a bad history of sepsis. The fact that even this weak scar was strong enough for one successful subsequent labour, and the invisibility and impalpability of the scars in the 18 repeated sections, presented a strong case against a serious view of the probabilities of rupture of the Cæsarean scar. He considered the causes of rupture of the scar to be: (1) sepsis; (2) faulty suturing; (3) the use of catgut for sutures, involving absorption before union was secure owing to vigorous autolysis in a rapidly involuting uterus. He suggested that only when the technique could be trusted, the puerperium had been afebrile, and if no abnormality or obstruction was present, could natural labour be allowed with comparative safety. The history was the all-important factor, and especially the old temperature chart.

Dr. AMAND ROUTH (London) said that when, in 1910, he collected 1282 cases of Cæsarean section performed by over 100 obstetricians and gynæcologists then living, beginning with a Cæsarean section performed by Dr. Lloyd Roberts in 1867, the risk of rupture of the scar in subsequent pregnancies was briefly discussed, more particularly from the point of view of whether sterilisation of the patient was justifiable or desirable. In 1910 the mortality of Cæsarean section for contracted pelvis in clean cases was under 3 per cent., and the risk of repeated Cæsarean section in anticipated cases was even less, but 14 out of the 100 operators advised sterilisation to avoid the danger of rupture of the scar in subsequent pregnancies. In this century "not sterilised" operations had increased considerably, leading to more subsequent pregnancies and repeated Cæsarean sections. Of 669 "not sterilised" cases of Cæsarean section for contracted pelvis 112 cases had become pregnant. Of these 112 pregnancies 108 ended in repeated Cæsarean sections (some more than once), and 3 had a subsequent rupture through the scar (Nos. 12, 37, and 38 in Mr. Holland's list), a percentage of 2·6 per cent. However, Dr. Routh thought that there must have been many pregnancies and probably some more ruptures amongst the 354 "not sterilised" cases included in the last three and a half years of his series. Dr. Routh said that to encourage perfect union, if the position of the placenta could be determined or surmised, the incision should be made elsewhere, especially in "unclean" cases. It seemed clear that transverse fundal incisions were not advisable, partly because the placenta often spread on to the fundus. Professor Munro Kerr's case (No. 12 in Mr. Holland's series) was an instance of this complication. Cæsarean section should be performed at full term or at the earliest indication of labour, so as to secure perfect uterine retraction. Intra-uterine sepsis was doubtless a cause of imperfect union of the incised muscles, especially if the incision had been made through the placental site. Sepsis, even with suppuration of the wound, did not necessarily prevent further pregnancies or repeated Cæsarean section. In one of Dr. Routh's cases repeated attempts at delivery by forceps had been made during the previous 48 hours. Septic sloughs had appeared on the child's head and round the abdominal wound, and a utero-abdominal fistula had resulted. This was closed when an appendix operation was subsequently performed The patient had since had two children delivered by Cæsarean section As to sutures, in 1910 catgut was used for both deep and superficial sutures by 27 operators, whilst 41 used silk and 8 silkworm gut Dr Routh agreed with Mr Holland that theoretically silkworm gut was the safest material to use for the deep sutures

Dr CARLTON OLDFIELD (Leeds) said that catgut had been used in Leeds for two generations and he was sorry to see it attacked Of his 41 patients he had himself visited 30, and 7 more had answered questions by letter, so that the results in 37 cases were known Of these, 20 had had no pregnancy after the Cæsarean section Three had had natural labour at term, and one of these—whose Cæsarean section had been performed for an ovarian cyst—had been through three full term pregnancies since her operation Three patients were now pregnant In all 21 patients had become pregnant again Dr Oldfield believed that the exaggerated importance attached to the operation by patients and sometimes even by the profession, contributed indirectly to the relative sterility, since precautions were adopted to prevent a recurrence of pregnancy He considered that by explaining to patients the safety of the operation the emotional factor, which made for artificial sterility, could be controlled He did not consider catgut to blame for rupture—the important point was avoidance of an infected wound The patient's second operation should be undertaken before labour set in There were many objections to the use of silk sutures, and the possible immediate results, such as a more septic wound, should be borne in mind His objection to Professor Munro Kerr's suggestion was that there would be extreme tension of the scar if natural labour took place, beside the greater likelihood of infection

Dr HERBERT SPENCER after expressing his appreciation of the valuable papers read by Mr Holland and Professor Munro Kerr, regretted that the work had not been carried out on the same scale and general plan as that adopted by Dr Routh It was a pity that the series was not made continuous with Dr Routh's, and that the cases in which the first operation was performed before 1912 were excluded Dr Spencer had performed 66 Cæsarean sections and 13 repeated Cæsarean sections, and had never met with a case of ruptured scar He did not think it ought to occur in an aseptic case *properly sutured* He regarded adhesions in an aseptic case as due to faulty technique His practice was to use carbolised floss silk of moderate thickness for the deep sutures, and then a continuous fine silk suture passed parallel to the incision, taking a double grip of the peritoneum and superficial layer of muscle, so that the deep sutures were buried and no suture at all was shown He regarded this method of suture as far superior to the Lembert or mattress sutures He strongly condemned the use of catgut, as it was impossible to ensure its sterility He considered silkworm gut too thin for closing the Cæsarean section wound as it was apt to cut the tissues

Dr Spencer drew the attention of members to the results in eclampsia Of 12 cases delivered by Cæsarean section 5 only became pregnant subsequently, and in 2 of these the scar ruptured with a fatal result He considered that Cæsarean section was rarely justifiable for eclampsia, and suggested that Cæsarean section was now being performed too often on inadequate grounds In general he agreed with the dictum, "Once a Cæsarean section, always a Cæsarean section" As to the retro vesical incision, he saw no advantage in its use in aseptic cases, but it might be useful in certain infected ones, especially if stitched up with silver wire left long and subsequently removed through the os The value of this incision would have to be decided by carefully recorded cases, with due reference to its effect on the time taken in delivery and the condition of the child

Dr BLAIR BELL considered that of the three causes of rupture sepsis was the most prominent If the placenta was on the anterior wall it was difficult to sew up the wound properly The position of the placenta could often be recognised by the presence of blood vessels on the uterine wall, and the site of the incision could be chosen accordingly The factor of autolysis of the muscle was unavoidable The technique used was often faulty, a mattress suture with overstitch as described in his recent lecture (THE LANCET, May 8th, p 993) was preferable to the interrupted suture As to suture material, Dr Bell believed silk to be quite unsuitable, but approved of chromic catgut He had tried Professor Munro Kerr's method In the first case he had found it simple and easy, and the wall was not so thin as was suggested by some Very rapid extraction was possible—a leg should be found and pulled out first He preferred a trap door incision  as a transverse one did not give enough room He approved of strong hypochlorite solution for sterilising the parts In another case a network of varicose veins covered the area he had wished to incise, so that he had to extend his original skin incision upwards He concluded that Professor Munro Kerr's method was unsuitable because it was not always possible to use it, and the decision could not be made till the uterus was exposed

Dr E O CROFT (Leeds) had had no personal experience of rupture of the uterine wound following Cæsarean section, but considered that the effective closure of the wound so that union of the whole thickness of the muscular wall was brought about with the formation of a minimum scar tissue was the important point in prevention He was a champion of the silk suture In two cases in which the patient had died of other causes, and he had occasion to examine the uterus, there was perfect union of the uterine wall and no trace of silk to be found In one of these cases in which the patient had contracted gonorrhœa and had become pregnant pyosalpinx was found, and though infection ensued the wound itself, sutured with silk, still held The stitches should not be more than ½ inch apart, should be inserted with a fully curved needle, should be entered and brought out at a good distance from the cut edges, and should include peritoneum but not decidua

Dr G FURNEAUX JORDAN (Birmingham) had done 19 repeated Cæsarean sections, and in three cases a third operation, but had never seen a rupture He used one continuous catgut suture, and had only once been able to find the previous scar, though he always made his incision in the mid line He was struck by the large relative sterility in Mr Holland's figures He agreed with Dr Oldfield's view as to its chief cause, and habitually reassured the patient at the first operation He never refused to perform a Cæsarean section on grounds of previous examinations outside, and had had only one death from sepsis He always poured a big jug of biniodide through the uterus

Dr FOTHERGILL was inclined to agree with the American belief that one Cæsarean need not necessarily be followed by another, provided that the patient was kept under observation during her next pregnancy, and that the operation had not been done for mechanical obstruction He did not believe the particular type of suture used to be of great importance, nor did he think it was necessary to sterilise the uterus As regards Professor Munro Kerr's method, Dr Fothergill said that he always made his uterine incision high so that the two incisions, abdominal and uterine, were not opposite each other

Dr W GOUGH (Leeds) had had experience of 100 cases—all done for contracted pelvis—of which 18 patients had had two and 5 patients three Cæsarean sections He had never had a rupture, but had seen thin scars He always used catgut in a continuous suture in two layers He would like to hear the proportion of ruptures in cases operated on for contracted pelvis only, as in the newer indications for Cæsarean section, such as eclampsia or ante partum hæmorrhage, the muscle might be weakened by toxæmia or exhaustion

Dr J W BRIDE (Manchester) described the Subsequent Reproductive Histories of 190 Cases of Cæsarean Section from St Mary's Hospitals, Manchester, during the period 1912–18 The total cases in the period under investigation communicated with were 241, replies were received from 190 cases Of these, 94 subsequently became ordinary and chromic gut. His objections to the incision advocated by Professor Munro Kerr were (1) its greater difficulty; (2) its proximity to the source of sepsis.

Dr. H. S. **Davidson** (Edinburgh) had not had a rupture, but his series did *not* include many cases. Silk and linen thread were used in his hospital. The decision as to the treatment of the subsequent pregnancy and the timing of the repeated Cæsarean, if performed, was very difficult.

Dr. J. D. **Barris** (London) said that the subject under discussion was a vital one. If it could be shown that the uterine scar was liable to rupture, our attitude to the classical conservative Cæsarean section would have to be profoundly modified. The cases had been collected not only for the limited period of 1912–18, but every case recorded at the hospital up to July, 1919, was included. The results were:—

Total number of Cæsarean sections (excluding sterilised cases)	81	
Number of cases treated	48	—i.e., 59%
,, ,, in whom no subsequent pregnancy occurred	20	,, 41%
Number of cases who subsequently became pregnant..	28	,, 59%

Results of pregnancies:—

Delivery by natural passages	4
,, repeated Cæsarean section	22
,, abortion	1
Now pregnant	1
Rupture of scar	0

The method of suture employed was a buried interrupted silkworm-gut. Cæsarean section had been performed several times upon the same patient without untoward result. Dr. Barris pointed out that catgut was used in 15 of the cases of rupture collected by Dr. Holland and that sepsis occurred in about half the cases. In his opinion there was not sufficient evidence to show that the relative sterility was the result of Cæsarean section. He concluded that we were justified in performing the classical operation. Rupture was rare provided catgut was not used and that sepsis did not supervene. Should sepsis occur he suggested excision of the scar at a later date as a precautionary measure.

Dr. L. G. **Phillips** (London) said that, excluding sterilised and fatal cases, 60 Cæsarean sections had been performed since 1912 at the Middlesex Hospital. Of these 60 cases 39 had remained sterile and 21 had subsequently become pregnant, of whom 14 had had repeated sections, 3 had had subsequent natural labours, 2 had had miscarriages, and 1 was pregnant at the present time. There had been 1 case of rupture of the scar. The interesting features of the analysis were the high sterility percentage, unexplained, and the special interest of the rupture case. With regard to the condition of the scar in repeated sections, 4 cases had had three and 11 cases had had two repeated sections, making in all 19 repeated sections. In 1 case only was the scar seen as a thin line; in the other 18 cases the scar was invisible and impalpable, and healing was apparently perfect. A most interesting feature was the anterior placental implantation in every case of repeated sections, though in the first sections the placenta was often posterior. It had been maintained that implantation on the scar was harmful, through the trophoblastic action of the placenta or the liability to retro-placental hæmorrhage. Dr. Phillips suggested that the very reverse might be true, for a thick placenta might act as an internal splint to the scar, and tend to prevent thinning of the scar region in labour. Moreover, the uterine musculature of the scar region, because of its apposition with the placenta, would not be subjected to the same muscular strain in labour as the rest of the uterus. If this were not so, uterine retractions and contractions would lead to premature separation of the placenta, which was not common. Of the 60 cases 39 had remained sterile for from two to seven years, mostly three years or over, and, excluding cases where precautions had been taken, the percentage still worked out at 52. There was no indication that pyrexia in the puerperium was a causative factor, for 68·4 per cent. of the sterile cases had an afebrile puerperium, while 27 per cent. of those subsequently pregnant had pyrexia in the puerperium. Age and parity appeared to have no influence, as half of the sterile cases were primiparæ in the twenties. The frequency of recurring pregnancies with repeated Cæsarean section indicated that the operation itself was not to blame; latent gonorrhœal infection might play a part. Perhaps this sterility and delayed pregnancy represented Nature's attempt to allow time for consolidation of the scar. Unless the cause could be discovered and removed, such a high sterility percentage might become a powerful factor limiting the scope of the operation.

Dr. Phillips then described the case of rupture. The patient had had very severe pyrexia in the puerperium, with suppuration of uterine and abdominal wounds, from which she nearly died. The interesting feature of the case was that the patient had been delivered naturally of a full-term child one year after the operation, and only at the second pregnancy did the scar rupture. In Dr. Phillips's opinion a natural labour should not have been allowed in a case with such a bad history of sepsis. The fact that even this weak scar was strong enough for one successful subsequent labour, and the invisibility and impalpability of the scars in the 18 repeated sections, presented a strong case against a serious view of the probabilities of rupture of the Cæsarean scar. He considered the causes of rupture of the scar to be: (1) sepsis; (2) faulty suturing; (3) the use of catgut for sutures, involving absorption before union was secure owing to vigorous autolysis in a rapidly involuting uterus. He suggested that only when the technique could be trusted, the puerperium had been afebrile, and if no abnormality or obstruction was present, could natural labour be allowed with comparative safety. The history was the all-important factor, and especially the old temperature chart.

Dr. Amand **Routh** (London) said that when, in 1910, he collected 1282 cases of Cæsarean section performed by over 100 obstetricians and gynæcologists then living, beginning with a Cæsarean section performed by Dr. Lloyd Roberts in 1867, the risk of rupture of the scar in subsequent pregnancies was briefly discussed, more particularly from the point of view of whether sterilisation of the patient was justifiable or desirable. In 1910 the mortality of Cæsarean section for contracted pelvis in clean cases was under 3 per cent., and the risk of repeated Cæsarean section in anticipated cases was even less, but 14 out of the 100 operators advised sterilisation to avoid the danger of rupture of the scar in subsequent pregnancies. In this century "not sterilised" operations had increased considerably, leading to more subsequent pregnancies and repeated Cæsarean sections. Of 669 "not sterilised" cases of Cæsarean section for contracted pelvis 112 cases had become pregnant. Of these 112 pregnancies 108 ended in repeated Cæsarean sections (some more than once), and 3 had a subsequent rupture through the scar (Nos. 12, 37, and 38 in Mr. Holland's list), a percentage of 2·6 per cent. However, Dr. Routh thought that there must have been many pregnancies and probably some more ruptures amongst the 354 "not sterilised" cases included in the last three and a half years of his series. Dr. Routh said that to encourage perfect union, if the position of the placenta could be determined or surmised, the incision should be made elsewhere, especially in "unclean" cases. It seemed clear that transverse fundal incisions were not advisable, partly because the placenta often spread on to the fundus. Professor Munro Kerr's case (No. 12 in Mr. Holland's series) was an instance of this complication. Cæsarean section should be performed at full term or at the earliest indication of labour, so as to secure perfect uterine retraction. Intra-uterine sepsis was doubtless a cause of imperfect union of the incised muscles, especially if the incision had been made through the placental site. Sepsis, even with suppuration of the wound, *did not* necessarily prevent further pregnancies or repeated Cæsarean section. In one of Dr. Routh's cases repeated attempts at delivery by forceps had been made during the previous 48 hours. Septic sloughs had appeared on the child's head and round the abdominal wound, and a utero-abdominal fistula had resulted. This was closed when an appendix operation was subsequently performed. The patient had since had two children delivered by Cæsarean section. As to sutures, in 1910 catgut was used for both deep and superficial sutures by 27 operators, whilst 41 used silk and 8 silkworm gut Dr. Routh agreed with Mr. Holland that theoretically silkworm gut was the safest material to use for the deep sutures.

Dr. CARLTON OLDFIELD (Leeds) said that catgut had been used in Leeds for two generations and he was sorry to see it attacked. Of his 41 patients he had himself visited 30, and 7 more had answered questions by letter, so that the results in 37 cases were known. Of these, 20 had had no pregnancy after the Cæsarean section. Three had had natural labour at term, and one of these—whose Cæsarean section had been performed for an ovarian cyst—had been through three full-term pregnancies since her operation. Three patients were now pregnant In all 21 patients had become pregnant again Dr. Oldfield believed that the exaggerated importance attached to the operation by patients and sometimes even by the profession, contributed indirectly to the relative sterility, since precautions were adopted to prevent a recurrence of pregnancy. He considered that by explaining to patients the safety of the operation the emotional factor, which made for artificial sterility, could be controlled. He did not consider catgut to blame for rupture—the important point was avoidance of an infected wound The patient's second operation should be undertaken before labour set in. There were many objections to the use of silk sutures, and the possible immediate results, such as a more septic wound, should be borne in mind. His objection to Professor Munro Kerr's suggestion was that there would be extreme tension of the scar if natural labour took place, beside the greater likelihood of infection.

Dr. HERBERT SPENCER, after expressing his appreciation of the valuable papers read by Mr. Holland and Professor Munro Kerr, regretted that the work had not been carried out on the same scale and general plan as that adopted by Dr. Routh. It was a pity that the series was not made continuous with Dr. Routh's, and that the cases in which the first operation was performed before 1912 were excluded Dr. Spencer had performed 66 Cæsarean sections and 13 repeated Cæsarean sections, and had never met with a case of ruptured scar He did not think it ought to occur in an aseptic case *properly sutured*. He regarded adhesions in an aseptic case as due to faulty technique His practice was to use carbolised floss silk of moderate thickness for the deep sutures, and then a continuous fine silk suture passed parallel to the incision, taking a double grip of the peritoneum and superficial layer of muscle, so that the deep sutures were buried and no suture at all was shown. He regarded this method of suture as far superior to the Lembert or mattress sutures. He strongly condemned the use of catgut, as it was impossible to ensure its sterility. He considered silkworm-gut too thin for closing the Cæsarean section wound as it was apt to cut the tissues.

Dr Spencer drew the attention of members to the results in eclampsia. Of 12 cases delivered by Cæsarean section 5 only became pregnant subsequently, and in 2 of these the scar ruptured with a fatal result He considered that Cæsarean section was rarely justifiable for eclampsia, and suggested that Cæsarean section was now being performed too often on inadequate grounds. In general he agreed with the dictum, "Once a Cæsarean section, always a Cæsarean section." As to the retro vesical incision, he saw no advantage in its use in aseptic cases, but it might be useful in certain infected ones, especially if stitched up with silver wire left long and subsequently removed through the os The value of this incision would have to be decided by carefully recorded cases, with due reference to its effect on the time taken in delivery and the condition of the child.

Dr. BLAIR BELL considered that of the three causes of rupture sepsis was the most prominent If the placenta was on the anterior wall it was difficult to sew up the wound properly. The position of the placenta could often be recognised by the presence of blood-vessels on the uterine wall, and the site of the incision could be chosen accordingly. The factor of autolysis of the muscle was unavoidable. The technique used was often faulty, a mattress suture with overstitch as described in his recent lecture (THE LANCET, May 8th, p. 993) was preferable to the interrupted suture. As to suture material, Dr. Bell believed silk to be quite unsuitable, but approved of chromic catgut He had tried Professor Munro Kerr's method. In the first case he had found it simple and easy, and the wall was not so thin as was suggested by some. Very rapid extraction was possible—a leg should be found and pulled out first. He preferred a trap door incision  as a transverse one did not give enough room. He approved of strong hypochlorite solution for sterilising the parts. In another case a network of varicose veins covered the area he had wished to incise, so that he had to extend his original skin incision upwards He concluded that Professor Munro Kerr's method was unsuitable because it was not always possible to use it, and the decision could not be made till the uterus was exposed

Dr. E. O. CROFT (Leeds) had had no personal experience of rupture of the uterine wound following Cæsarean section, but considered that the effective closure of the wound so that union of the whole thickness of the muscular wall was brought about with the formation of a minimum scar tissue was the important point in prevention. He was a champion of the silk suture. In two cases in which the patient had died of other causes, and he had occasion to examine the uterus, there was perfect union of the uterine wall and no trace of silk to be found In one of these cases in which the patient had contracted gonorrhœa and had become pregnant pyosalpinx was found, and though infection ensued the wound itself, sutured with silk, still held The stitches should not be more than ½ inch apart, should be inserted with a fully curved needle, should be entered and brought out at a good distance from the cut edges, and should include peritoneum but not decidua

Dr. G FURNEAUX JORDAN (Birmingham) had done 19 repeated Cæsarean sections, and in three cases a third operation, but had never seen a rupture. He used one continuous catgut suture, and had only once been able to find the previous scar, though he always made his incision in the mid line He was struck by the large relative sterility in Mr. Holland's figures. He agreed with Dr. Oldfield's view as to its chief cause, and habitually reassured the patient at the first operation He never refused to perform a Cæsarean section on grounds of previous examinations outside, and had had only one death from sepsis. He always poured a big jug of biniodide through the uterus.

Dr. FOTHERGILL was inclined to agree with the American belief that one Cæsarean need not necessarily be followed by another, provided that the patient was kept under observation during her next pregnancy, and that the operation had not been done for mechanical obstruction. He did not believe the particular type of suture used to be of great importance, nor did he think it was necessary to sterilise the uterus. As regards Professor Munro Kerr's method, Dr. Fothergill said that he always made his uterine incision high so that the two incisions, abdominal and uterine, were not opposite each other.

Dr. W GOUGH (Leeds) had had experience of 100 cases—all done for contracted pelvis—of which 18 patients had had two and 5 patients three Cæsarean sections. He had never had a rupture, but had seen thin scars. He always used catgut in a continuous suture in two layers He would like to hear the proportion of ruptures in cases operated on for contracted pelvis only, as in the newer indications for Cæsarean section, such as eclampsia or ante partum hæmorrhage, the muscle might be weakened by toxæmia or exhaustion.

Dr. J. W. BRIDE (Manchester) described the Subsequent Reproductive Histories of 190 Cases of Cæsarean Section from St. Mary's Hospitals, Manchester, during the period 1912–18. The total cases in the period under investigation communicated with were 243, replies were received from 190 cases. Of these, 91 subsequently became pregnant, of whom 3 were delivered by the natural passages, 68 had repeated Cæsarean sections, and 1 had a rupture of the Cæsarean scar; 13 had aborted and 21 were now pregnant. Of the 96 cases who had not become pregnant again, 22 cases took precautions against pregnancy, 4 cases were widowed, 3 cases died of non-pelvic conditions at a later date; in one case the husband had been on active service since the operation. The remaining 66 state that they took no precautions. Fifty-three of the 96 patients had pyrexia of greater or less degree after the operation. Of the 4 cases where natural delivery had been attempted 1 died of rupture of the Cæsarean scar. The other 3 were cases of slight pelvic contraction. Two had living children, and 1 a craniotomy and subsequently another Cæsarean. In each of the 68 cases of repeated Cæsarean sections the indication had been contracted pelvis, with the following five exceptions: large child, 1; eclampsia, 1; fibroid, 1; recto-vaginal fistula, 1; overdue pregnancy with excessively large child, a monster, 1. Twenty-one cases were allowed to go into labour, and 47 cases were not in labour. In only 1 case was silk used. Forty-four cases had some degree of pyrexia. In the case of rupture of the scar, the patient, aged 23, was admitted on Nov. 24th, 1916, with an ovarian cyst obstructing labour. Dr. Fletcher Shaw performed Cæsarean section and right ovariotomy. Early in 1919 she was seen by Dr. Shaw, who decided to let labour proceed normally as there was no pelvic contraction. On May 14th, 1919, the patient was admitted in labour at 2.40 A.M. in good condition. At 5 A.M. she had some very strong pains and slight bleeding from the vagina. At 8.15 A.M. she had a running pulse of 140, and a subnormal temperature. On abdominal palpation it was obvious that the uterus was ruptured, and the abdomen was immediately opened. The child was free in the peritoneal cavity and dead. The uterus was inverted through the old scar, which had ruptured, and the placenta was adherent to the inverted uterus. The peritoneal cavity was full of blood. The child and placenta were rapidly removed, the inversion corrected, and supravaginal hysterectomy performed as quickly as possible. The patient died at 7 P.M. from collapse and shock.

Dr. Bride concluded from the cases investigated by him that precautions against pregnancy probably accounted for much of the relative sterility after Cæsarean section, especially as included in the 66 cases who are put down as "no precautions" were many who evaded answering this question at all. Of the 21 cases now pregnant, several showed an interval from child-bearing corresponding with the interval of absence of the husband on active service. Abortions did not seem to follow Cæsarean section with any marked frequency. No definite conclusion as to the safety of allowing a post-Cæsarean uterus to be subjected to the strain of labour could be drawn from the statistics of St. Mary's Hospitals, Manchester. In Dr. Bride's opinion, however, it appeared doubtful if it could ever be good practice to subject a scar in an organ so liable as the uterus to excessive distension and powerful contraction, to the strain of labour. With regard to suture media, with perhaps half a dozen exceptions, two layers of catgut, sometimes chromicised, had been used in all the cases in that series. He thought that the figures showed that repeated Cæsarean sections might be undertaken many times with impunity, and that the risk in the early stages of labour appeared negligible. He had assisted Dr. Fletcher Shaw to perform Cæsarean section for the seventh time on the same patient last year. She had been in labour four or five hours before operation, and the uterus, though adherent, was well healed. She was sterilised on that occasion.

Mr. **CLIFFORD WHITE** (London) said that two theoretical considerations had an important bearing on the suture joining the Cæsarean incision. Firstly, the uterus was the seat of intense autolysis, as was shown by the weight diminishing from about 2 lb. to 2 oz. in a few weeks. This autolysis was most rapid in the first few days, and it was not fair to expect an absorbable suture like catgut, standardised for absorption in ordinary muscle, to withstand digestion in an organ where autolytic action was proceeding with such violence. Secondly, a continuous suture was unsuitable for holding the wall of the uterus in close apposition, because the uterus was involuting at the rate of over $\frac{1}{2}$ inch in 24 hours. Hence a 5-inch uterine incision was only 3 inches long on the fourth day, and any continuous suture must become slack and incapable of holding the uterine wall closely united. This applied to some extent to the use of mattress sutures. As the uterus was diminishing so rapidly in size the interrupted sutures must be tied much more tightly than was usual in other surgical procedures, or they would become loose in a few days. The rhythmic contractions and relaxations of the uterus would accentuate this tendency. It would seem, therefore, on theoretical grounds that a weak scar was particularly likely to occur: (1) with catgut, and (2) when continuous sutures were employed; conversely, a strong scar should result when a non-absorbable interrupted suture was employed. Mr. White had personal experience of 70 cases of Cæsarean section. Of these, eight were Cæsarean hysterectomies, leaving 62 cases in which the scar might yield. None were sterilised. In every case he had used interrupted sutures of silk or linen thread. He had never seen or heard of any yielding of the scar in any of these cases. Of the 62 cases, seven had had more than one Cæsarean operation—two patients having Cæsarean section performed three times and five twice. In each case the scar was sound, and in only one was it easily noticeable. In addition to these, several cases had come to his knowledge where patients had had normal or forceps deliveries after Cæsarean sections for eclampsia or placenta prævia, and in no case had there been symptoms or signs of rupture. In one case of Cæsarean section for eclampsia in two successive pregnancies the scar was not found to be weakened when seen at the second operation, showing that toxæmia did not necessarily cause imperfect uterine union in all cases.

Dr. **FLETCHER SHAW** said he used chromic catgut, but found Mr. Holland's figures convincing. There might, however, on further analysis prove to be a different explanation for the ruptures.

Dr. **LAPTHORN A. SMITH** (London) said a few encouraging words on the success attending Cæsarean section. He feared lest the figures given might unduly depress the younger members present.

In reply, Mr. **HOLLAND** expressed surprise that all the members were not now convinced of the influence of the suture material on rupture. He preferred silkworm-gut to silk. In reply to Dr. Spencer he had excluded cases operated on for the first time before 1912 because it would have been impossible to tell which of the scars had ruptured.

Professor **MUNRO KERR**, in answer to Mr. Clifford White, said that no cystitis had occurred in any of his cases. In answer to Dr. Blair Bell, he did not see why placenta prævia should interfere with his method, as an ordinary incision was often made inadvertently over the placental site with no bad results.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM: ANNUAL CONGRESS.

THE Annual Congress of this society took place in the rooms of the Royal Society of Medicine on April 29th and 30th, and May 1st, under the presidency of Mr. J. B. STORY, P.R.C.S.I.

President's Address.

The teaching and examination of medical students in ophthalmology formed the subject of the President's address. He said: The Council of British Ophthalmologists have already urged the General Medical Council to adopt two reforms—first, to make three months' attendance at an ophthalmic clinic obligatory, and, secondly, to have an examination by ophthalmic surgeons as part of the final pass examination. The General Medical Council accepted the first and rejected the second—a most astonishing thing to those who know well that medical students have no time to waste on subjects that are not necessary and in which examination is not compulsory. There are two reasons why a certain knowledge of ophthalmology is necessary for every person permitted to practise: (1) because the vast majority of practitioners cannot escape from having to diagnose and treat diseases of and injuries to the eyes when no specialist can be obtained; and (2) because in many serious diseases the evidence afforded by ocular conditions is most important, and often the ocular symptoms are those which induce the sufferer to seek medical advice. For instance, interstitial keratitis may be the first evidence of infantile syphilis, even before the eruption of the teeth described by Jonathan Hutchinson; and acquired syphilis may show itself in the choroid, iris, or retina long after the patient has forgotten the primary disease completely. Ocular tuberculosis may be the first visible manifestation of that disease, and the ocular signs are important in tabes, disseminated sclerosis, meningitis and other intracranial lesions, diabetes, nephritis, arterio-sclerosis, to mention only a few serious and not uncommon affections. In many of these the ocular signs may be mainly naked-eye appearances or fairly easily observed ophthalmoscopic lesions.

The final decision of the General Medical Council is said to be that the hospitals should, or may, refuse certificates to students who do not acquire sufficient knowledge, thus shuffling off the responsibility thrown on it by Act of Parliament and placing it, not on the licensing bodies over whom it has control, but on the medical staffs of hospitals. It has been objected that if an examination in ophthalmology is instituted at the Final it will overload the curriculum, and that other special branches of surgery will claim a similar privilege. As regards the first objection, the special clinical examination has been the rule in every one of the Irish licensing bodies for some 30 years and has not caused overloading. As regards the second, it has been already pointed out how great is the importance of ocular signs and symptoms in serious constitutional diseases, an importance much greater than can be assigned to any of the other organs usually taken up as specialties. Ophthalmic surgeons are not narrow-minded, and would certainly urge that every medical man should be able to recognise anomalies of ear, nose, and throat which can be seen with such simple instruments as the common head-mirror and aural speculum.

The speaker insisted upon the necessity of a practical clinical examination, as in his experience of now 30 years as an examiner he had found students whose book knowledge was perfect unable to diagnose quite simple ocular anomalies in the patients before them. The General Medical Council should be urged by the society to reconsider its recommendation, and institute the following reforms: 1. That each candidate for a licence to practise should be compelled to attend an ophthalmic clinic for a period of three months. 2. That the Final examination should include, as a separate pass subject, a clinical examination by ophthalmic specialists. If the Ophthalmological Society is unsuccessful, it is hoped that the general practitioners throughout Great Britain will take the matter up.

Contributions and Functions.

Contributions were read on Thursday, April 29th, by, among others, Mr. C. H. Usher and Mr. John Rowan, whose paper on the Non-operative Treatment of Glaucoma led to an interesting debate in which Mr. Treacher Collins, Mr. A. Zorab, Sir Anderson Critchett, Mr. Harrison Butler, Dr. G. Mackay, Mr. Rayner Batten, Mr. Richardson Cross, Mr. Gray Clegg, Mr. R. Cruise, Dr. A. Hugh Thompson, Mr. Bishop Harman, Mr. B. Cridland, and the President took part.

There was a wealth of clinical material shown at the Royal London Ophthalmic Hospital, City-road, and St. Margaret's Hospital, under the Metropolitan Asylums Board, concurrently with the Congress. On Thursday afternoon members visited Moorfields, when Mr. Percy Flemming lectured on the Neighbourhood of Moorfields in Former Days, with the aid of lantern-slides and maps. The lecturer was cordially thanked for an interesting discourse.

On Friday morning Sir Archibald Garrod and Mr. R. Foster Moore opened a discussion on Diabetes in Relation to Eye Diseases, in which Dr. O. Leyton, Dr. F. J. Poynton, Mr. H. P. Adams, Dr. P. J. Cammidge, Dr. C. O. Hawthorne, and Mr. R. R. James, among others, took part. Papers were read by Mr. H. M. Traquair, Dr. Gordon Holmes, Mr. M. L. Hine, Mr. Ernest Clarke, Mr. Humphrey Neame, and Mr. W. Wallace.

On Saturday morning the members visited St. Margaret's Hospital, which is devoted, under the Metropolitan Asylums Board, to the study of ophthalmia neonatorum, when after an inspection under the direction of Mr. M. S. Mayou, a full discussion took place on the prevention of the disease, opened by Dr. G. Fitzgibbon, Master of the Rotunda. Mr. Mayou, Dr. Scharlieb, Dr. Elizabeth Macrory, Mr. Sydney Stephenson, Dr. Maitland Ramsay, Dr. J. Wharton, and Mr. A. L. Whitehead were among those who contributed to the debate.

Mr. TREACHER COLLINS proposed the following resolution, which was carried unanimously:—

"The Ophthalmological Society of the United Kingdom wishes to urge on the Metropolitan Asylums Board, now that so large a number of cases of ophthalmia neonatorum are aggregated in one institution, that facilities should be afforded at it for the teaching of medical students, midwives, and district nurses as to the natural history and treatment of the disease."

The members of the Congress dined together on the opening evening.

THE ASSURANCE MEDICAL SOCIETY.

A MEETING of this society was held on May 5th, Dr. T. D. LISTER, the President, in the chair.

Sir THOMAS OLIVER read a paper on

Gastro-intestinal Operations and their Sequelæ, especially Cancer, from a Life Insurance Point of View.

After some introductory remarks the lecturer proceeded:

Gastro-duodenal ulceration is a serious condition. Life is only saved and health regained in many instances by short-circuiting the route from the stomach to the jejunum. Even where the operation has been successful, we can hardly regard the life as a normal one from an insurance point of view. Some offices probably do not accept such lives at all. Too little time has passed since the operation became a recognised means of treatment for sufficient experience to have been gained and data collected for us to speak absolutely upon this point, for although three or four years may have been spent in comparatively good health by a patient since his operation certain accidents may yet arise at the junction or close to the site of operation, which may undo all the good achieved. What are these accidents? Like many of you, I am consulted fairly frequently by patients upon whom gastro-enterostomy has been performed, and who are no better for the operation. There is always the possibility of fresh peptic ulceration taking place, not so much in the stomach itself as in the jejunum, and due to the rush of acid chyme into this portion of the intestine. Again, ulceration may occur at the junction—a stitch or two may have given way rather prematurely, and thus created a minute chink in which the acid contents leaving the stomach exert a harmful influence. There is, too, the possibility of adhesions forming, while yet another possibility is that of cancer. It is this question of growth as a sequence to gastro-jejunostomy which led me to prepare this paper in the hope that it might be discussed at this meeting and that light might be thrown upon this important subject. A few months ago I examined a client for life insurance who had had gastro-jejunostomy performed upon him, and as I had recommended acceptance of the life as an invalid one for a limited period of years with a slight loading, the head office suggested that in a large percentage of patients thus operated upon cancer subsequently developed at the site of the operation. This has not been my experience, neither has it been that of our local surgeons, nor of the Royal Victoria Infirmary. The sequel of malignant disease following upon gastric operation, apart from the fact of cancer existing at the time of the operation, has not been observed in the North of England. As the subject is important from a life insurance point of view, I asked for further details from the head office, and received the following:—

"(1) The principal medical officer stated that, as regards operation for duodenal ulcer, the disease might or might not occur on a future occasion; it might lead to stricture and ulceration, or the scar left after the operation might degenerate into cancer.

> (2) Another of the medical examiners was of the opinion that if the ulcer did not heal, bleeding or perforation might take place, and that a fresh ulcer *might* form at the site of operation or cancer develop.
>
> (3) Another examiner wrote that fresh ulceration might take place at the site of gastro-enterostomy, adhesions might form, or, as a later but not a common event, a malignant growth might develop.
>
> (4) A fourth examiner was of the opinion that the following complications may follow operations for duodenal ulcer—internal hernia, rather a rare event, and perforation in 2 per cent."

Cancer as a Sequela to Gastro-enterostomy.

To me the replies, so far as malignancy is concerned, were not helpful. Cancer was only referred to in such a way as to suggest that the statements were not based upon experience. I therefore wrote to my infirmary colleagues, and here are their replies. Mr. J. W. Leech says, as the result of 20 years' experience as an operator in gastro-duodenal diseases:—

> "Cases of malignant disease are recorded, but such is not my experience. It would, however, be reasonable to presume that some cases primarily regarded as simple ulcer were, in fact, malignant at the time of operation."

Another surgical colleague, Mr. Gray Turner, writes:—

> "If cancer follows, it must have been present at the time of operation and been overlooked. Although not unknown, it is so rare for cancer to develop after the operation as to make it certain that it had arisen *de novo*. After gastro-enterostomy there are fresh dangers which may become a menace to longevity—viz., jejunal and gastro-jejunal ulceration in 2 to 5 per cent."

The experience of my infirmary colleagues is in conformity with my own—viz., that if cancer is subsequently found at or close to the site of any of the operations I have alluded to, it is more than probable that it was present, but not diagnosed, at the time of the operation. I wrote to Sir Harold Stiles, of Edinburgh, and asked him what sequelæ he had found after gastro-enterostomy, and he replies:—

> "I have only seen two ulcers follow gastro-enterostomy; they were both at the seat of anastomosis. ...... I have had no experience of cancer following gastro-jejunostomy."

Mr. Henry M. W. Gray, of Aberdeen, writes:—

> "No case has come under my notice of cancer developing at the site of gastro-jejunostomy operations. ...... I think the condition must be a very rare one, else we should have heard much more about it ere this."

Sir Kennedy Dalziel, of Glasgow, writes:—

> "I have nine cases of cancer of stomach after operations for gastro-enterostomy, but in no case did the tumour originate at the new orifice, though simple ulcer has been noted in five cases there. Most of the malignant cases have developed eight to ten years after the gastro-enterostomy on the site of the original ulceration. I have not had any ulceration at the anastomosis since I gave up clamps and used three rows of stitches, now about 15 years ago."

Sir Kennedy Dalziel's experience is very interesting. It confirms the view expressed by some pathologists that cancer occasionally develops upon an old ulcer. There has been an opinion expressed by some French physicians that pulmonary phthisis occasionally follows upon gastro-enterostomy, but of this I have no experience.

To obtain further information upon this relationship of gastro-jejunostomy and cancer I wrote to Dr. Homer Gage, of Worcester, Mass., U.S.A., Medical Director of the State Mutual Life Insurance Co. In a pamphlet entitled "Surgery of Gastric and Duodenal Ulcers in Relation to the Insurance Risk," he states, after alluding to the possible recurrence of symptoms years afterwards, that the

> "study of living pathology made possible by gastric surgery has revealed gastric ulcer as the forerunner, if not the cause, of a very large proportion of gastric cancers."

Experience in America.

In the Clinic of the brothers Mayo 71 per cent. of gastric cancers presented evidence of a previous ulcer; also in many instances, where the ulcer had been excised at the operation, microscopical examination showed that malignant disease had already commenced. What the Mayo experience shows is this—that at the operating table it is not always easy to tell, by naked-eye appearances, a simple ulcer from one in which cancerous changes have already commenced, and that since on microscopical examination in what appeared to be a simple ulcer there is frequently found evidence of ulcer, malignancy has probably been present from the first. Of the two sites of ulcer, gastric and duodenal, the duodenal seemed to the Mayo brothers to be the one less likely to be followed by malignant disease. If malignancy is concealed in what appears to be a simple ulcer at the time of operation, two circumstances suggest themselves. One is that we would expect the cancerous growth to reveal itself sufficiently as to be recognisable within at least two years after the operation, and the other is the advisability of excising simple ulcers. Our experience in the North of England is that malignant disease follows short-circuiting so infrequently as to be discountable. Since there is a discrepancy between British and American experience in regard to this question, there may probably be at work other factors than those which relate only to the operation. The incidence of cancer is, I believe, greater in America than it is in this country. It may be, too, judging from Sir Kennedy Dalziel's experience, that the incidence of cancer among the general population is greater in Glasgow than it is in Edinburgh and Aberdeen, and, if this is the case, the circumstances cannot altogether be ignored as playing a part in the varying experiences of surgeons as regards post-operation gastro-intestinal cancer.

The Risk of Cancer in Recommending Acceptation for Insurance.

The question I submit to you is not alone whether cancer is a frequent after-event at the site of gastro-intestinal operations, but one involving larger issues, such as the insurability of persons who have had operations performed upon any part of the alimentary canal. As regards appendicectomy, for example, there is not the least doubt that a man without an appendix is freer from risks than a man who still owns one, and yet few insurance offices would regard a man who had had a serious internal operation performed upon him as a first-class life. And to some extent there is a reason for this, for the appendix in a few instances has been the seat of cancer at the time of operation, and, but for microscopical examination, might simply have been regarded as an inflamed tube. This circumstance therefore suggests the inadvisability of accepting lives which have been operated upon for appendicitis until at least three or four years have elapsed since the operation. On the other hand, since malignant disease so infrequently follows upon operations for appendicitis, and competition between insurance offices is keen, some examiners might feel disposed to recommend acceptance of the life as early as one year after the operation, if young and otherwise healthy, with an addition, which should automatically decline and disappear after a limited number of years, provided that the health of the applicant has been improved by the operation.

Insurability after Gastro-duodenal Ulcer without Reference to Malignancy.

Reverting to the subject of insurability of persons operated upon for gastro-duodenal ulcer, and in this instance without reference to malignancy, Mumford found in 147 cases of gastro-enterostomy for ulcer of the stomach that in 17 per cent. the end result was "bad." Sir Berkeley Moynihan, drawing his experience from 186 cases upon which he had operated for duodenal ulcer, states that from an insurance point of view 12 per cent. are unsatisfactory; while Graham, taking his figures from the Mayo Clinic, found of 438 patients operated upon for duodenal ulcer and 162 for gastric that 12 per cent. and 20 per cent. respectively were unsatisfactory from an insurance point of view. It is not to be inferred that any one of the patients was the subject of post-operative malignant disease, but that they were simply not improved by the operation. That surgical intervention in gastro-duodenal ulcer has saved many lives and transformed thousands of invalids into active, cheerful, and healthy men and women goes without saying. Sir Kennedy Dalziel informs me that one of his patients 25 years after the operation remains quite well. In one of his patients who died from disease—not of abdominal origin—nine years after operation the pyloric orifice had become almost obliterated, but the duodenum remained patent, and it had apparently been functioning normally. Ninety-five per cent. of the Mayo patients were alive and well at the end of three years. Successful as gastro-intestinal surgery is, we not only still require more data to guide us to a conclusion, but each life must be dealt with on its own merits.

Given an applicant who has been subjected to gastro-enterostomy, whose health is good, and whose physique is in no way injured, I think such a life might be accepted, with a fair addition, for a limited period of years—say, 15 or 20, according to age, family history, and general physical condition, on the understanding that if the applicant survived that period a portion of the extra premium might be returned in the form of a bonus. This might not be quite consistent with the principle of average which is the basis of life insurance. It might be found impracticable to return a portion of the extra premiums to those who had survived and out-reached the 15 or 20 years suggested. On the other hand, would it be fair to saddle the survivors with the burden thrown upon the office by those who died within, say, five years after the operation? I do not know the intricacies of actuarial methods, but is it necessary to create sectional invalid insurance and to load any one section with its own burden, or is it preferable to distribute the risk over the total number of lives insured, after a supposed limit of safety has been reached? One other way suggests itself, and it is to load the life heavily with an extra premium for the first five years, after which, the risk having been covered, the policy might be regarded as normal for the age reached by the insured person.

Discussion.

Mr. **McAdam Eccles** said that gastro-jejunostomy for pyloric obstruction of a simple nature was one of the most satisfactory of gastric operations, and although there should be a loading for the first five years, it might be remitted afterwards provided the "life" remains in good health. Gastric ulcers might heal. He was doubtful as to a duodenal ulcer healing without surgical aid, but he thought gastric ulcers were more doubtful from an insurance point of view because of their liability to malignant disease. Carcinoma at the actual site of the anastomosis in a gastro-enterostomy must be exceedingly rare. With regard to adhesions and intestinal obstruction following abdominal operations, they were liable to occur even after gastric operations. They certainly occurred after appendicular suppuration, and by no means infrequently after hysterectomy. Hence a history of any operation of these varieties should raise the suspicion of possible adhesion and possible intestinal obstruction and the "life" should be loaded in many instances.

Dr. THEODORE THOMPSON said that one very important sequel of abdominal operations had not been given the importance it deserved in Sir Thomas Oliver's paper. The formation of adhesions after abdominal operation was very common and, unfortunately, intestinal obstructions not uncommonly followed. Dr. Thompson examined a case for life insurance recently. Four years before the subject had had a severe operation for an appendicular abscess, but he had been quite well since; in view, however, of the severe nature of the appendicitis five years were added. Six weeks after the examination he was seized with severe abdominal pain and acute intestinal obstruction, the result of an adhesion in the right iliac fossa. Dr. Thompson therefore strongly advised that in cases of appendix operation, where abscess has been present, the "life" should be loaded. He pointed out that not only do adhesions follow appendicular operations and other pelvic operations, but they also occur after operations for gall-stone and gastric trouble.

The PRESIDENT pointed out the importance, from the point of view of insurability, of the freedom from symptoms after the operation.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this society held on April 15th Dr. RUPERT HALLAM read a paper on

The Therapeutic Uses of Radium.

After a brief description of the chemical and physical properties of the metal he explained the methods employed in estimating the quantity of radio-activity in the various applicators used in medicine and surgery. The strength of each applicator supplied by the Sheffield Radium Institute is always described in terms of radium metal, and he suggested that it would be a great advantage for the comparison of doses and results if this unit of dose was universally adopted. Although the Sheffield radium purchased in 1915 was primarily intended for the treatment of inoperable malignant disease, it had also been extensively used for the treatment of certain skin diseases. In his experience the results obtained in the treatment of rodent ulcer (providing the ulcer did not involve the bone or conjunctiva) were good. He had latterly employed carbon-dioxide snow in conjunction with the radium, and anticipated a higher percentage of non-recurrences. Thirty-three cases of cavernous nævi treated during the year 1919 had all responded exceedingly well, and he maintained that this method superseded all others. A large number of cases of malignant disease had been treated by the surgeons of the four voluntary hospitals in Sheffield during the last four years from radium supplied by the Sheffield Radium Institute. Sarcoma apparently responded more favourably than carcinoma to the application of radium, and four cases which had been free from recurrence for periods varying from one to four years were shown at the meeting. The results of the treatment of carcinoma of the cervix had been disappointing. In no case of carcinoma of the mouth could improvement be said to have occurred. In conclusion, Dr. Hallam maintained that apparent cure of inoperable malignant disease by radium was exceedingly rare, but that it often relieved pain, lessened discharge, and gave patients a ray of hope.

At the close of the paper several members related their personal experience of the treatment of malignant disease with radium. Dr. MILES PHILLIPS had found it of little value in carcinoma of the cervix. He expressed the opinion that equally good results were obtained by curetting the growth, and he related a case in which this method had been employed and the growth remained quiescent for four years.—Dr. G. WILKINSON described several cases of sarcoma of the tonsil which had responded well to the treatment and were apparently free from disease.—Mr. ARCHIBALD CUFF had employed it in two cases of menorrhagia with satisfactory results.

Reviews and Notices of Books.

A STUDY OF THE LONG BONES OF THE ENGLISH SKELETON.

By KARL PEARSON, F.R.S., and JULIA BELL, M.A. Part I.: "The Femur," Chapters I. to VI., Drapers' Company Research Memoirs, Biometric Series X., quarto, text and atlas, 30s. net; Part I., Section II.: "The Femur of Man, with Special Reference to other Primate Femora," Chapters VII. to X., Appendices, Bibliography, and Indices, Biometric Series XI., quarto, text and atlas, 40s. net. Cambridge University Press. 1919.

IT requires no special knowledge on the part of anyone walking in a London street, where may be met casually all types of all nationalities, to distinguish between a Negro and a Chinaman, an Indian and an Italian, an Englishman and a Japanese, and correctly to identify them. But if the skeletons of representatives of these same races are submitted to an observer, he will have to acquire a special experience before he can confidently express an opinion upon the racial characteristics displayed by the bones Yet, if he sets about his task in the proper way it is possible for the anatomist to arrive at conclusions from the examination of mere bones at least as accurate as those of the man in the street who picks out representatives of living races and correctly "places" them. But it is the method of science to strive after exactness, and the objective expression of its results in figures; and for the last century anatomists have been measuring bones and endeavouring to express in angles and proportions the distinctive peculiarities of individual bones, and the statistical meaning of figures obtained from comparing large collections of bones. The aim of such procedures was primarily to give numerical expression to distinctively racial characters that could be appreciated by the observer: but in course of time most anthropologists came to pay more attention to measurement and less to the appreciation of racial traits. Through sheer laziness they spared themselves the bother of study and observation, and simply recorded the measurements of bones—often made merely by a laboratory servant, and did some crude arithmetical juggling with the figures so obtained. One has only to glance through the pages of any anthropological journal to realise that this is no exaggeration of the state of affairs. But the mathematician then interposed with the claim that if anthropology was a mere question of statistics it was clearly essential that the treatment of the figures obtained by measuring bones should at least be conducted in accordance with the approved methods of statistical science. For the last quarter of a century Professor Karl Pearson's school of biometricians has been showing biologists how figures should be dealt with scientifically, and has been trying to impress upon them that if biology is nothing more than measurement—as much of their writings seemed to suggest—something more than kindergarten arithmetic was needed to extract any sort of meaning from the figures.

Incidentally Professor Pearson has built up a great school of applied mathematics, and has shown biologists how figures should be treated, and how significant are the results that can be obtained by such objective methods, even from the plastic and ever-changing forms and proportions of living beings. The Department of Applied Statistics of the University of London has just entered upon the occupation of the magnificent biometric laboratory provided largely by the enlightened generosity of the Drapers' Company at University College. Professor Karl Pearson has signalised this important event by issuing four large quarto volumes dealing with the femur, the results of a research started more than 12 years ago "merely with the intention of illustrating the application of biometric methods to a special field of anthropometric inquiry." This work marks an epoch in the application of mathematics to the interpretation of the data of anthropometry, and provides invaluable guidance to the anatomist who is set with the task of determining the meaning of one of the classes of the data which he collects.

In his preface Professor Karl Pearson tells us:

> "The earlier stage of this memoir embraces the first five chapters—these chapters are essentially an illustration of the application of biometric methods to the study of a single long bone. With the remaining chapter of Part I. the transition begins, for as we started to study the individual characters of the human femur, we found ourselves led on to consider not only such characters in other races than the English, but also in the anthropoids and ultimately in a wide range of primates."

When Professor Pearson has achieved so vast a reform as the inculcation of truly scientific methods in the domain of biological statistics, it is peculiarly unfortunate that he should have marred this magnificent work and been led into grave errors by his attacks on anatomists and the biological method. While freely admitting that anthropologists who rely upon statistics and argue from figures in a grotesquely inadequate manner fully deserve to have the puerilities of their arithmetic exposed, one cannot be blind to the fact that in trying to carry the war into the anatomists' camp Professor Pearson has himself perpetrated much graver faults in biology than the mathematical lapses he is castigating in the work of the biologists. The statistical method may be particularly valuable for giving exact numerical expression to each character of a bone, for summing up its features, and expressing the extent of its conformity to the group to which it belongs. But it is clear from the suggestions made in this monograph that the biometric method is a hazardous and misleading guide to the interpretation of kinship and affiliation. We shall quote only one instance of the fallacies for which a reliance upon the statistical method must be held responsible, but it is of so flagrant a character as to make one deeply regret that Professor Pearson embarked upon such treacherous seas. He tells us that "accordingly the suggestion may be made that the *Cebidæ* are derived from a form approximating to the Tarsiidean, and the *Simiadæ* from a form approximating to the Lemurine group of the Lemuroids" (Sect. II., p. 314). However great the divergence of opinion may be as to the exact stages through which the descendants of some Eocene Tarsioid form passed to become an ape, all zoologists would unite in repudiating the possibility of a Lemurine ancestry for the apes. In a number of other instances the statistical method yields results that more nearly accord with the facts of biology; but the suggestions expressed in the series of diagrams in the latter part of Section II. make the reader sceptical of the usefulness of a method which can mislead so gravely. These criticisms are necessary lest a reform which transforms anthropometry from the plaything of dilettanti into the severe discipline of a real science should be seriously compromised, as it will be, if it is to be used as a guide to phylogeny, where it clearly is quite untrustworthy.

The authors define their ideas as to the value of biometric methods in anthropology in the following sentences (p. 257):—

> "No form of anthropometry can be reasonably successful in racial differentiation if the measuremental functions do not adequately express changes *in the racial character.* It is the racial character which first appeals to the eye, and it is the business of the anthropometrician to be quite certain before he takes into general use any measuremental function that it really does reproduce numerically the phases of the character he desires to discriminate. ...... [*Statistical work in anthropometry*] is absolutely primary and the only road to safe generalisation. When the statistical and the appreciative methods are placed side by side, the former being based on fitly chosen measuremental functions, there cannot be for a moment a doubt as to which will give the better results—that is *evidenced in every case by the ultimate appeal of the appreciative* anthropologists to the very statistical methods—generally imperfectly handled—which they started by endeavouring to discredit."

But in making these claims the biometricians seem to forget that the aims of the statistical and the appreciative methods are not identical. Each method provides information which is complementary to that afforded by the other, and it is futile to call one primary and the other secondary unless the precise object of the work is clearly and specifically defined. Take, for example, the case of the anthropologist who is working in conjunction with an archæological party. His function is to estimate the age and determine the sex of the remains; to decide whether the body has been subjected to post-mortem treatment of any kind and, if so, to investigate its nature; to record the position of the bones and to decide whether displacements are due to the action of gravity in a decomposing corpse and, if not, what the significance of the disturbance is; to study peculiarities of structure, whether they are due to congenital causes, injury, or disease; and, finally, to form an appreciation of the distinctive individual traits of the body and assess their racial, social, and other significance. These are aims that do not come within the scope of the statistician's functions, which are to assess the degree of conformity of this individual with groups of similar remains of known age and provenance. It is merely quarrelsome to insist that one of these functions is of primary and the other of secondary importance.

Putting aside these defects, into which the authors have been led by a not unnatural wrath aroused by slovenly work on the part of certain anthropologists, we can only admire the vastness of the scheme of work suggested by this great monograph and the thoroughness with which the enormous labour of expressing in figures the femur's distinctive features has been carried out. After working through this formidable array of mathematical learning the reader feels that there is still a good deal of the femur's character that is not expressed in the figures. For the bone is part of a living organism in a perpetual state of flux; it is constantly being rebuilt and refashioned in accordance with a multitude of factors that cannot be expressed merely in figures. Professor Karl Pearson is to be congratulated on the excellence of the two volumes of plates, and the way in which the volumes have been produced.

MEDICINE AND THE ALLIED SCIENCES.

By SAMUEL FOMON, Ph.D., M.D., Major, Medical Reserve Corps, U.S.A. London and New York: D. Appleton and Co. 1919. Three volumes and key with desk index. Pp. 2684. £5 10*s*.

THIS is a text-book—or rather a compendium of many text-books—presented in an original way for the benefit of the student whose memory, it is hoped, will be systematised by its use. The method consists in giving "general outlines" in the form of central memorisable data around which the special peculiarities of each subject can be grouped. The advantages claimed are as follows: (1) To convey in the briefest time-saving manner all that is known about a given subject; (2) to impress such knowledge upon the reader's memory in logical sequence and to show the inter-relations of all divisions of medical study; (3) to instruct a student how to weave together these various facts into a complete study of each disease and its treatment, whether it be medical or surgical. The compilation has evidently been a labour of love to the author, and to those who in their early days found delight in Mr. Bradshaw's correlation of times and events will make a successful appeal. But to the mind that lives not by ratiocination alone these three bulky volumes may prove a little burdensome. The text and illustrations are clear, there are some useful lists and tables, and every medical library would find the book useful for reference.

ORIGINE, EVOLUTION ET TRAITEMENT DES MALADIES CHRONIQUES NON CONTAGIEUSES.

By J. DANYSZ. Paris: J. B. Baillière et Fils. 1920. Pp. 132. 5 francs.

IN this short monograph the author sets forth the theory that certain chronic non-contagious diseases such as urticaria, asthma, and the like, are due to the presence of a protein antigen in the intestine, and that the treatment therefore should be carried out on anti-anaphylactic principles. The first part of the book consists of a short, simple description of the phenomenon of anaphylaxis and the theories of mechanism and causation. The second part deals with a series of cases treated by the author, starting from the standpoint that the diseases in question are due to an error of metabolism, in which the intestine fails to deal naturally with albuminoid substances and bacterial proteins, and in which, therefore, a protein antigen is assumed to be present The author s method of treatment is a course of subcutaneous inoculations of autogenous or stock mixed vaccines of intestinal bacteria, including coliform bacilli, enterococci, unidentified diplococci, and streptococci There are 260 cases recorded They include cases of urticaria, eczema, psoriasis, asthma, neurasthenia, albuminuria, dysmenorrhœa, menopause, mucous colitis, intestinal toxæmia, dyspepsia constipation, chronic rheumatism, in fact, most of the heterogeneous collections of obstinate chronic complaints which are generally associated with neurotic individuals The third part of the book deals with immunity in relation to anaphylaxis

Unfortunately, vaccine therapy will not cure all the chronic illnesses of man, and we have so frequently been disappointed in the past that we have learnt to adopt an attitude of suspicion, though we shall watch the course of this treatment with much interest

A TEXT BOOK OF INDIGESTION

By Dr G HERSCHELL Fourth edition, revised and rewritten by ADOLPHE ABRAHAMS, O B E, M D Camb, M R C P London Edward Arnold 1920 Pp 228 10*s* 6*d*

THE first 68 pages of the late Dr George Herschell s book, which has been remodelled and rewritten, deal with the process of normal digestion, the nature and causation of indigestion, and the investigation of the patient The latter includes the usual routine examination, also all the modern methods of investigation—intragastric technique, test meals, X ray examination, examination of the stools—and one is particularly glad to see that the inquiry into the history and symptoms of the patient receives special attention A short account is thus given of the subject the matter being well selected and described A consideration of organic diseases of the stomach then follows This is an addition to the volume, former editions dealing only with functional disorders It is disappointing to find that they are treated of in a short and sketchy manner more reminiscent of a text book of general medicine than of a special treatise on the stomach, so that the alteration hardly seems to be justified However, a considerable amount of useful information will be found, more particularly in the sections devoted to treatment All forms of functional disorder are regarded as of nervous origin, except "acute indigestion,' which may be due to the ingesta in a normal individual, or otherwise occurs in an exhausted subject, or one suffering from "congenital relative hepatic insufficiency" The classification of nervous indigestion is that usually given in text books Gastric atony and gastroptosis are both described under the heading of "sensory disturbances,' which is no doubt an oversight Pancreatic indigestion and gastric disturbances due to disease outside the stomach are shortly referred to The appendix on the preparation of foods remains substantially unaltered

EVENING PLAY CENTRES FOR CHILDREN

By JANET PENROSE TREVELYAN London Methuen and Co 1920 Pp 182 5*s* net

PERHAPS Mrs Humphry Ward s most abiding work consisted in her wide eyed sympathy for the London child From the Passmore Edwards Settlement in Tavistock place the movement for starting schools for invalid children originated as well as this fruitful idea of evening play centres Dealing mainly with the beginnings in London, Mrs Trevelyan also describes the impetus given by recent official recognition and grants to the movement throughout the country Chapters on vacation schools and organised playgrounds also sketch these cognate and important topics We are shown how the out-of school education of the city child may be of greater social importance than its academic curriculum The need merely to relieve existing miseries of childhood is very pressing A care committee of South London stated (p 29) that it had carefully investigated the cases of 100 children from one school, and that 67 of these were found locked out of their homes till 7, 8, or even 9 o clock at night And of these 67, one third were under 7 years of age This was borne out by an appeal received from the owner of a jam factory in the same district, who offered to defray part of the cost of a play centre, if it could be established near his works, because the children used to come down to the factory gates in the evenings and cry till their mothers came out The successful teaching of these little vagabonds is related —how steadily and with great perseverance social responsibility and the need to play the game by their neighbour was woven into their conscience Attendance being purely voluntary, the children go because they want to do so An evening s exclusion is a punishment for the unruly or disobedient When we read of one centre (Stepney) attracting an attendance of over 1100 in an evening it is evident that someone was putting in effort and cost, but it was only after 20 years, as the book records, that London awoke to the fact that the playtime of her children was her own concern Now half the cost is borne by the Board of Education and half the remaining cost by the London Authority so that one quarter of the money spent in this movement has still to be found by voluntary effort The movement has a wide public future before it towards recreational development for the whole community The schools are destined to become social centres of the greatest importance in national economics, for play is nature s education of the senses and emotions Here especially is there the opportunity for moral training The neglect in cities cannot be allowed to persist That way lies social unrest.

The book will be widely read and deserves careful study What Mrs Ward in the preface says of London —that there are 32 centres in being and 200 needed—applies with equal force to the rest of the country in both its urban and its rural districts

JOURNALS

British Journal of Children s Diseases Vol XVII January March Edited by J D ROLLESTON M D —In a paper entitled 'Some Observations on the Medical Treatment of Infantile Paralysis ' Dr Charles Mackay emphasises the importance of early diagnosis in the treatment of this disease In the early stages he condemns massage and electricity as not only useless but harmful and recommends immediate and complete anatomical rest for the paralysed muscle He considers that muscle re education should not be begun until pyrexia pain and tenderness have ceased and should be continued for the next two years at least —Mr T H Gunewardene reports a case of Leukæmia with Scalp Nodules, with a description of the post mortem examination —In an article on Preleukæmia in Infancy Dr Gordon Ward gives an account of the condition described by Professor Martelli of Naples This writer has given the name of preleukæmia to a large class of cases sometimes denominated von Jaksch s disease sometimes leukanæmia or pseudo leukæmia or secondary leukæmia and characterised clinically by anæmia and splenomegaly According to Professor Martelli these cases are potentially leukæmic and if the disease is not checked by treatment may die of leukæmia The preleukæmic condition may rise from several factors such as syphilis tuberculosis sepsis, or malaria acting on an inherently defective organism Dr Ward however is of opinion that the unknown cause of leukæmia in the adult never produces anything but leukæmia in the child and that the cause of preleukæmia in the child will never produce the adult form of leukæmia even in the adult —Dr W J Rutherfurd reports a case of Cardiac Angina in a child of 6 years the anginal attacks being due to pericarditis and has collected other instances from literature There was no history of rheumatism or chorea in his case —In a paper on Some Clinical Forms of Typhus Fever in Children Dr A Stroe of Bucharest states that typhus in children is generally mild its duration being usually from 7 to 12 days In 25 per cent of the cases the eruption is absent, in other cases it is transient or very sparse In some cases however especially in children over 7 years of age the exanthem presents the same characters as typhus in the adult Bronchitis is frequent but areas of congestion are exceptional in children Signs of profound intoxication are extremely rare The diagnosis may thus present great difficulties, but considerable help is afforded by the Weil-Felix reaction.—Dr. T. McCririck reports a case of Tuberculosis Verrucosa Cutis of the Foot in a boy, aged 12, who had probably been infected by his sister, who was suffering from multiple tuberculous abscesses.—A case of Isolated Disease of Tarsal Scaphoid: Köhler's Disease, is recorded by Mr. P. Maynard Smith.—A case of Congenital Redundant External Meatus; Repeated Abscess-Formation; Excision, is related by Dr. Dan McKenzie, who has been unable to find more than eight other cases on record of this congenital malformation. In the majority the orifice and external meatus are described as being divided by a septum or partition into two canals, one of which ends blindly, while the other leads to the tympanic membrane. Abscess formation does not seem to have been encountered in any previous case.—The abstracts from current literatnre are devoted to acute infectious diseases and dermatology and syphilis.

Reports and Analytical Records

FROM

THE LANCET LABORATORY.

COLLOSOLS.

(BRITISH COLLOIDS, LTD., 22, CHENIES-STREET, LONDON, W.C. 1.)

COLLOIDAL preparations are increasing in interest from the therapeutic point of view, it being freely claimed that the usual medicaments are more effective when presented in the form of a "sol." This conclusion is based on the fact that the vital processes of the organism are colloidal. The medical profession have now to deal with the claims set out. There are several preparations at their disposal for such an inquiry, as is evidenced from the specimens of "sols" recently submitted to us by the above company, which include collosol quinine, iodine, argentum, sulphur, and manganese. The chemical behaviour of these preparations is peculiar. They do not respond in some instances in the way that the classic salts do, and, we imagine, would give much trouble to the student asked to determine in an examination what active constituent (metallic or non-metallic) was present. With well-recognised reagents, for example, the colloidal preparations of the metals give negative or confusing results. The colloidal state must be got rid of before the normal reactions of ordinary salts can be obtained. This, of course, shows that a different physical condition exists when the element is in the colloidal form. Colloidal quinine, for example, is not immediately bitter to the taste, nor does it give a fluorescent solution when sulphuric acid is added. Collosol argentum does not yield the usual precipitate of silver chloride when hydrochloric acid is added, though chloroform takes out some iodine from collosol iodine, and caustic soda and a lead salt present with collosol sulphur soon yields a conspicuous darkening due to formation of lead sulphide. The therapeutic advantages suggested by the use of "sols" are of interest, and the claim that the activity of the medicament is greatly increased, requiring a much smaller administrative amount for a definite effect, will attract attention. So far as we know, there is no evidence as to the fate of the "sol" in the gastric or intestinal secretion. Should there be any reversion the view of the increased therapeutic efficacy of the "sol" could hardly be sustained. These preparations afford an interesting study under the ultra-microscope, and medical men are invited to inspect recent innovations in this direction.

NUTRESCO PREPARATIONS.

(NUTRESCO, LTD., NUTRESCO HOUSE, DOLBEN-STREET, BLACKFRIARS, LONDON, S.E. 1.)

The foundation of the "Nutresco" products is meat substance hydrolysed by a special and improved process. Nutresco is thus sharply differentiated from meat extractives, and in fact consists chiefly of albumoses and peptones. The product is contained in several preparations, including a malt combination, a syrup, an invalid food, chocolate, biscuits, and wines. The fluid preparations turn solid when bromine water is added, proving the presence of a high proportion of proteoses, and the wines gave a big precipitation with the same reagent. The malt admixture showed marked diastasic action, and the invalid food on analysis gave the high figure of 24·0 per cent. of proteins, due to both casein and digested meat substance. The chocolate contained, according to our analysis, 10·0 per cent. of protein. These preparations are correctly described, and offer a choice of special nutrient material to the medical practitioner.

(1) COD-LIVER OIL; AND (2) FRUITINE CONFECTION.

(ALLEN AND HANBURYS, LTD., BETHNAL GREEN, LONDON, E.)

1. There has, of course, been some disturbance during the war in regard to the supply of cod-liver oil, and it is of interest to note that the normal supplies are being restored, and the above firm announce that their "new season's" (1920) oil is of good standard quality, and that the livers are yielding rather over the average percentage. The oil contains the maximum amount of unsaturated fats and the minimum of free fatty acids. The sample submitted to us certainly shows a high standard, and the vendors have probably satisfied themselves as to its growth-promoting constituent (the fat-soluble factor). 2. The "fruitine confection" has a well-known laxative fruit basis, and is free from artificial purgatives. It is quite pleasant to the taste, and infants and young children, we are informed, show no objection to taking it. In preparation care is taken to preserve the accessory factors of the fruit intact.

AMBRIODIN (CENTAUR).

(THE CENTAUR CHEMICAL CO., LTD., BASSISHAW HOUSE, BASINGHALL-STREET, LONDON, E.C. 2.)

We have confirmed the composition of this compound which contains ammonium bromide (5 gr.), potassium iodide (1 gr.), combined with a laxative. The formula is well known to medical men as of use in bromide treatment, but the tablet offers a convenience in administration. Advantages are claimed in the treatment of epilepsy by this combination as opposed to the exclusive use of potassium bromide.

DOLS' (VOLATALISE) FLANNEL.

(DOLS AND CO., LTD., HUDDERSFIELD.)

There is some novelty in the suggestion of the application of this fabric as a therapeutic measure. It is purely and simply flannel impregnated with a certain iodine compound which yields iodine to the affected part, particularly when in contact with a moist skin, as during exercise. Claims are made in favour of its employment in the alleviation of the pains of rheumatism, lumbago, and injured muscles. It will be interesting to receive an endorsement of these claims, but, at all events, iodine is recognised as a factor in relieving the class of disorders referred to, and the method of application suggested is convenient. The flannel is of a dark-brown colour and readily yields iodine on treatment with nitric acid.

MABELA.

(GOVERNMENT OF THE UNION OF SOUTH AFRICA, 90, CANNON-STREET, LONDON, E.C. 4.)

The analysis of this product was as follows:—

	Per cent.		Per cent.
Moisture	9·60	Fat	2·40
Mineral matter ...	1·60	Fibre	5·64
Protein	10·97	Sugar	2·69
Carbohydrates ...	67·10		

It is prepared from a seed grown in Natal known as mabela, which seems to be identical with millet. Locally the raw material is known as Kaffir corn, which has been used largely for the manufacture of beer. This beer has antiscorbutic properties, according to a report on scurvy in South African Native Labour Corps by Dr. Hamilton W. Dyke, published in THE LANCET of Oct. 19th, 1918. Large draughts of Kaffir beer, according to this report, conferred an immunity from scurvy upon the Kaffir troops. Germinating seeds are known to contain antiscorbutic materials. The meal we examined shows nutritive properties from a chemical point of view, but according to this examination it does not disclose an advanced malting stage, since the soluble matter in cold water only amounted to 5·75 per cent.

THE LANCET.

LONDON: SATURDAY, MAY 15, 1920.

A Dual Alliance against Venereal Disease.

EARLY in 1917 the Borough of Portsmouth opened a clinic for the treatment of persons suffering from venereal diseases, which has since been enlarged and is generally admitted to be doing good work. In February last Dr. A. MEARNS FRASER, medical officer of health for the Borough, presented to his Health Department a special report on means for the prevention of the same diseases. The chief duty of a sanitary authority is, as all will agree, preventive rather than remedial. In this able and, in parts, moving little pamphlet Dr. FRASER set forth the case for prevention, and concluded by recommending his local authority to take the necessary steps to spread a knowledge of the means of self-disinfection, so that those who insist upon satisfying their sexual appetites by promiscuous intercourse should be in a position to protect themselves, and possibly their innocent families, against loathsome disease. On March 3rd the *Portsmouth Health and Housing Committee* approved and adopted Dr. FRASER'S report and decided to urge the Council to empower them at once to act upon it. On April 27th the Council itself confirmed this decision, and the principle of popularising the methods of venereal prevention among the male population is now the official policy of the municipality of Portsmouth.

Where others have discussed Portsmouth has acted. The manifold difficulties and objections raised by both parties to a warm controversy have been more than sufficiently studied during the last few months. Some of the objections have been too much in the nature of Aunt Sallies stuck up expressly to be knocked down by cogent and clever argument. Advocates of self-disinfection are apt to assume as prevalent among their opponents the mediæval view in favour of retaining disease as a method of enforcing chastity. No responsible body of thinking people now takes this view or regards fear as a useful deterrent from venereal infection. Many of the opponents of self-disinfection profess to see nothing in it but the issue of prophylactic packets from an automatic machine. Setting aside bogies and bugbears, there remain two difficulties keenly felt by many who are not fanatics in regard to popularising self-disinfection. The first is in essence that in so far as the male genital tract is relatively easy to disinfect, and the female relatively difficult, to advocate self-disinfection is to set up that different moral standard as between men and women against which it is increasingly the spirit of the age to protest. It is said that to advocate a method of disinfection applicable only to men is to revive the spirit of the ill-famed C.D. Acts; in a word, to make fornication safe for men. To this it may be replied that whereas to fix a different moral standard is wilful, the anatomical difficulty is not of our own seeking, is at present inevitable, and is to be overcome by improvement in technique. Illustrations do not carry us far, but the analogy might be suggested of an armoury in which the curator, unable, as he would like, to enforce perfect orderliness on those using it, should yet insist that swords be cleaned after use in case they should be put back in the wrong scabbards. And in the end the scabbards would remain clean. The other real difficulty, also of a fundamental and reasonable nature, is felt by those who fear the effect of prophylactic propaganda upon the mind of the young man or woman growing up to the consciousness of virility and sexual potency. How can information be conveyed for making promiscuous intercourse safer from risk of infection without suggesting to the adolescent that his sanitary authority expects him to be clean but not continent? This is a crucial point to which earnest groups of seekers have devoted attention without as yet finding a solution of wide acceptance.

Portsmouth has cut the Gordian knot. Before the Council meeting all the omens were unfavourable to the acceptance of Dr. FRASER'S report except by a bare majority and in a controversial atmosphere. Wisely construing his duties as chief magistrate and first citizen, the Mayor of Portsmouth called a meeting at which the various conflicting interests were represented and which was addressed by Dr. FRASER. The reasonableness of the proposals struck home, and after very full discussion the supporting resolution (no formal vote was in order) was proposed by the Rural Dean, seconded by Bishop INGHAM, and supported by the President of the Free Church Council. With one corollary: that along with the municipal action in the domain of hygiene, there should run concurrently a voluntary campaign to promote chastity. Evidently some of those present at the meeting were not satisfied that they had done all that they could in social, educational, and moral directions. Dr. FRASER'S demand for a hygienic campaign undoubtedly precipitated a moral campaign. For the statistician this may be unfortunate, as the moral campaign will invalidate the hygienic as a scientific experiment. But for all other thinking people the prosecution of the two campaigns side by side may well suggest a solution for one of the most pressing problems of civilisation.

The Cæsarean Scar.

SINCE the magnitude and exhaustive nature of the task achieved by Mr. EARDLEY HOLLAND is only faintly reflected in the brief abstract of his paper at present available, the genesis of the discussion on Cæsarean section at the joint meeting of Obstetrical Societies, reported on pp. 1062–68 of this issue, may be recalled. In a letter dated Feb. 10th of this year, addressed to obstetric surgeons in active hospital practice throughout the country, Mr. HOLLAND sought the coöperation of his colleagues in an attempt to obtain definite information on the risk of rupture of the uterine scar after Cæsarean section. In order to ensure a uniform plan for this collective investigation he enclosed sample tables compiled from his "follow-up" records of cases from the London and City of London Maternity Hospitals under these headings: (1) Indication for and year of operation; (2) age of the patient; (3) her parity; (4) period of pregnancy or labour when Cæsarean section was performed; (5) the type of uterine incision; (6) the site of the placenta; (7) the method of suture and material used; (8) the presence, absence, or degree of pyrexia during convalescence; (9) the interval in years since the operation; (10) the condition of the infant; (11) whether precautions against pregnancy had been taken.

The 84 cases of Cæsarean section recorded in the sample tables, from which were excluded sterilised and fatal cases and those in which the first Cæsarean section had been performed before 1912, were divided into six groups. One group contained 49 cases who had no subsequent pregnancy, though unsterilised; another, 10 patients whose subsequent pregnancy culminated in delivery by the natural passages; a third included 15 cases who had repeated Cæsarean sections. Then followed 5 cases who aborted, 4 now pregnant, and 4 (a fifth case since recorded is included in Mr. HOLLAND'S account) whose scar had ruptured. Three cases appeared in more than one category. These were the figures given by Mr. HOLLAND in his original questionnaire to intending collaborators, where he suggested that these results, as far as they go, would seem to show: (1) that Cæsarean section is followed by relative sterility; (2) that rupture of the scar, though relatively rare compared with the number of Cæsarean sections, is not so rare when compared with the number of patients who subsequently become pregnant and go to term, and especially with the number in whom delivery by the natural passages occurs. So cordial was the response of the obstetric surgeons (one had himself traced out and visited 30 cases) not only in supplying material but in arranging it on the lines suggested, that Mr. HOLLAND was able to incorporate in his opening address figures received only a short time before its delivery.

The need for the investigation cannot be doubted. The discussion on the treatment of ante-partum hæmorrhage in the morning session of the same meeting showed clearly the increasing tendency to regard as indications for Cæsarean section conditions, such as eclampsia and placenta prævia, that may not recur. In these circumstances the dictum, "Once a Cæsarean section, always a Cæsarean section," quoted by one of the speakers, is open to question, provided the scar can be relied on to stand a subsequent labour. It was on the factors undermining the strength of the scar that the discussion chiefly turned. Professor MUNRO KERR advocated an alternative in position and direction to the classical uterine incision. Mr. HOLLAND regarded the material used for its suture as of primary importance, and though the number of actual ruptures is small the case against the catgut suture for this purpose seems strong. Reference to the discussion will show that most of the speakers were agreed on this point. A suggestion by Dr. J. D. BARRIS that in cases of doubtful asepsis with a febrile puerperium the scar should be excised at a later date deserves consideration in the rare cases in which a woman is sufficiently anxious for another child to submit thereto. No amount of reassurance by a doctor can really remove the terror of the word operation, aroused even by a suggested incision of an abscess. In this connexion the "unexplained" relative sterility after Cæsarean section seemed to cause surprise among some members, to whom this form of delivery appears a commonplace. The psychological cause emphasised by Dr. CARLTON OLDFIELD and Dr. FURNEAUX JORDAN surely affords sufficient explanation.

A very useful practical point emerged from the drawings of sections of ruptured scars shown by Mr. HOLLAND. In every case the muscle had retracted, and the scar consisted of fibrous tissue covered by peritoneum outside and endometrium inside. It is in these thin scars, which follow infection of the wound, that rupture is liable to take place. The old ununited muscle surfaces, covered by decidua and blood clot, are deceptively thick in the recently emptied and retracted uterus, and operators were warned by Mr. HOLLAND from his own experience not to mistake them for freshly torn surfaces and suture them together as being such. Only by a careful study of Mr. HOLLAND'S inquiry will its real importance become apparent. Certain members expressed regret that he had not gone two years further back and thus joined his figures to those collected by Dr. AMAND ROUTH in 1910. The connecting link may yet be supplied, but it would be ungrateful to expect still more back records from an observer who has, moreover, given excellent reasons for his self-imposed restrictions in scope. Even were his statistics of less intrinsic importance they would be of value as a model for collective clinical investigations which might with advantage be carried out in every branch of medicine and surgery.

Red Cross and the Voluntary Civil Hospitals.

A PUBLIC appeal is imminent emanating from the Joint Council of the British Red Cross Society and the Order of St. John of Jerusalem in England, supported by a general survey of the hospital situation throughout England and Wales written by Sir NAPIER BURNETT. It may be remembered that at the beginning of this year Sir ARTHUR STANLEY, presiding over a meeting held at St. Thomas's Hospital, of which charity he is the honorary treasurer, promised that the Red Cross Society and the Order of St. John would make the assistance of voluntary hospitals part of a great peace programme; and the survey which Sir NAPIER BURNETT has written proposes to show the volume of work done by the hospitals and their present financial position as a justification for the distribution of funds. The survey, as far as it at present goes, will not take the London voluntary hospitals into consideration, for they have the assistance of such great central organisations as King Edward's Hospital Fund for London and the Metropolitan Hospital Sunday Fund, among others; and there is a further fitness in this limitation, that the critical position of the metropolitan hospitals is already under the favourable consideration of the Government.

The survey, we are informed, will show the amount of work done during the year 1919 by each individual hospital and the income and expenditure and annual cost per bed, while spot maps will indicate the *locale* of the hospitals and the ratio of their beds to the surrounding populations. Upon such data the Red Cross Society and the Order of St. John will give their help, and a bold appeal will be made to the public for a sum of £1,000,000 per annum to be distributed in the form of grants supplementary to the individual efforts of the hospitals themselves. That this would be the policy shortly to be pursued has already been indicated in the columns of THE LANCET, and it is indicative also of what is known to be the intention of the Government in future legislation in respect of medical services. The magnificent work of the voluntary hospitals is to be supplemented and not supplanted.

It must be known that one way in which the charities might have helped themselves is economically barred. The depreciation in their invested funds is such that the sale of securities can be a wise one only in very exceptional circumstances. Any general realisation of these funds would mean a vast aggregate loss to the charities, as is shown in Sir NAPIER BURNETT'S scheme by the figures relating to a group of nine voluntary hospitals. We may be certain that the position indicated by these figures is typical of the story that many a hospital treasurer could tell.

The text of the scheme will be published in THE LANCET next week, and will, in the meantime, be in the hands of our readers as it appears in the daily press. We believe that they will agree with us in thinking that the cause of the hospitals will prevail with the public. Given a well-informed and sound scheme, the public will certainly come to the aid of the voluntary hospitals, whose work, be it understood, cannot possibly be wholly replaced in spirit or in scope by any State effort, though the needs of the sick and injured can be ministered to by money coming from the State, from the municipality, or from both.

◆

The Fellowship of Medicine.

THE Fellowship of Medicine is conducting a propaganda which is reaching into many of the largest medical centres, and the result has been a steady flow of inquiries regarding the possibilities of medical study in London, especially from Canada and the United States. This shows an interesting development of possible activities. The medical men who attended, and sometimes crowded, the courses arranged by the Fellowship in last year's session were chiefly serving in the armies; they were brought together in exceptional circumstances, and, in some instances, their military obligations dictated their post-graduate work. This season the graduates are entering the courses on their own initiative, and at their personal expense. Their number is still a matter of speculation with the executive, but each week, we are informed, adds names to the register. It cannot be too strongly insisted that the future of London as a great post-graduate centre will be largely determined by the opportunities offered to overseas visitors during the immediate future. The first call is, of course, for clinical demonstrations, and particularly for short intensive courses in special subjects, and we trust that these will be arranged without delay, for the greater the preliminary notice the easier will it be to answer the questions of inquirers, to complete lists, and to ensure order in the arrangements. A time-table should also be drawn up to cover the holiday season. Work slackens in London from the middle of July to the end of September; yet it is during this vacation period that many men will fit in a course of study, as is shown by the dates specifically mentioned in letters of inquiry. We hope that the enthusiasm behind the movement for making London a great post-graduate centre will be maintained; it received such a good send-off that the danger of relaxation of effort on the part of its supporters must be guarded against. The more energetically the organisation is befriended at the first the more sure will be its complete success in the near future. The English-speaking post-graduate wants to come to London for his studies, and his capital city should give him what he needs.

Annotations.

"Ne quid nimis."

THE DINNER TO SIR GEORGE MAKINS.

A COMPLIMENTARY dinner to Sir George Makins, President of the Royal College of Surgeons of England, and lately consulting surgeon to the British Expeditionary Forces, was held at the Wharncliffe Rooms of the Hotel Great Central on Monday evening last, Sir Cuthbert Wallace presiding. The large company was representative of the many directions in which Sir George Makins's learning, industry, and powers of organisation have been employed for the public good. His colleagues on the staff of St. Thomas's Hospital were there in force; Sir John Goodwin, Director-General of the Army Medical Department, and Sir James Porter, late Director-General of the Naval Medical Services, represented the long connexion with the two Services; Sir John Bland-Sutton was present not only as a personal friend but as Vice-President of the Royal College of Surgeons of England, which corporation was also represented by Mr. S. F. Cowell, the secretary; Sir Walter Fletcher for the Medical Research Council, Sir John MacAlister for the Royal Society of Medicine, Dr. Alfred Cox for the British Medical Association, and Mr. F. G. Hallett for the Conjoint Examination Board of the Royal Colleges, were also present with many professional leaders, brother officers, and personal friends. Mr. Max Page acted as honorary secretary to a thoroughly successful dinner.

The toast of the evening was given by Sir Cuthbert Wallace in simple terms of great intimacy. As pupil, as assistant, as hospital colleague, and as comrade in two great wars he was able out of personal knowledge to construct a telling picture of his friend and chief. The toast was seconded in four directions. Sir John Goodwin bore testimony to the enduring industry and unfailing tact of Sir George Makins in dealing with service problems and in conducting service work. Mr. E. F. White presented Sir George Makins as a model consultant for the general practitioner and for the patient alike, being wise, helpful, and generous. Sir John Bland-Sutton spoke of long association with Sir George Makins in promoting the study of clinical pathology, while assuring the audience that no one had ever better filled the dignified post of President of the Royal College of Surgeons of England. The last of the seconders was Sir George Savage, who appeared in the character of Sir George Makins's instructor in mental science and in the arts of fishing and mountain-climbing, and who gave a humorous sketch of life at Bedlam some 40 years ago. The proposer and the four seconders, though speaking from deliberately different points of view, managed to compose one portrait of a highly accomplished, determined, and sincere man, and to do this without any of the usual exaggerations. Even among a gathering largely composed of personal friends, Sir George Makins found it difficult to reply to such embarrassing and straightforward testimony to his merits; but he may rest assured that what was said of him at the complimentary dinner accords with what his professional brethren at large have for a long time said, and felt.

SOLUBLE LEAD IN CASSEROLES.

REFERENCE has already been made in THE LANCET[1] to the subject of soluble lead in casseroles made of glazed pottery ware. A number of these casseroles have now been examined, including specimens of French, English, and Dutch makes. With the exception of two makes, which were described as leadless glaze, all the casseroles yielded some soluble lead on boiling with a 1 per cent. solution of citric acid. The amounts of lead extracted varied from 0·3 to 19 mg. of lead monoxide per square decimetre of the glaze. The lead was not completely extracted by the first treatment, but continued to be extracted with each subsequent treatment. Some determinations were also made of the amount of lead extracted when fruit and vegetables were cooked in the casseroles. The results confirmed those obtained with the citric acid solution, and we hope to publish shortly the full details of the inquiry which was made at the Household and Social Science Department of King's College for Women by Miss Helen Masters.

ROYAL INSTITUTE OF PUBLIC HEALTH: THE CONGRESS IN BRUSSELS.

THE final programme of the Congress of the Royal Institute of Public Health, to be held in Brussels from Wednesday, May 19th, to Monday, May 24th, has now been agreed upon, and it is clear that the proceedings will be interesting and instructive. His Majesty the King of the Belgians will be present at the inaugural meeting on Thursday, at 11 A.M., in the Palais des Académies. A meeting of reception will be held in the same building on Wednesday, at 9 P.M., by the committee of organisation, to which delegates and members will be cordially welcomed. The executive of the Congress regret that owing to the shortness of time it has been impossible to send individual intimations.

MEDICAL PRACTICE IN NORWAY.

WE have received from a correspondent in Norway an account of a recent session of the Storthing at which the introduction of certain estimates for the coming Budget was made the occasion for a general review of the state of medical practice in town and country. The discussion centred about a supplementary vote of Kr.25,000 towards the pay of State medical officers, and the alternative of a vote of Kr.40,000. This was rejected, and the original sum of only Kr.25,000 was passed by a large majority. Judged by figures alone, this incident might be regarded as one of minor parochial interest; but it is significant as an index of the sentiments of the country towards the medical profession. Since the introduction of compulsory insurance against sickness, and the adoption of the principle of remuneration according to work done instead of by annual fixed sum for each insured person, there has been a considerable increase of material prosperity in the medical profession. Only in a few instances has the principle of payment according to work done been abused by medical men who have made much out of minor ailments. On the other hand, this principle has been an admirable incentive to conscientious treatment of ailments which were apt to suffer neglect under the old system of club sickness insurance. But the point on which the community at large is most at variance with the medical profession seems to be the neglect of country districts in favour of the towns, where every medical man can make a livelihood, even though the supply of doctors is in excess of the demand. Many large country districts, on the other hand, are left without any medical aid, although substantial grants by the Government and local authorities are made. It was pointed out in the Storthing that out of 150 new appointments in country districts, about 50 were vacant for want of applicants. Various remedies for this uneven distribution have been suggested, and Labour and Socialists have advocated the plan of financing the education of medical students who would, when qualified, be bound to serve an apprenticeship of so many years in the least populous country districts. But the more popular view seems to be that the system of subsidies should be strictly limited, and that by the automatic action of the law of supply and demand matters will soon right themselves. Already it appears that the improved economic status of the medical profession has resulted in a large influx of medical students to the University of Christiania, and it is anticipated that in a few years there will be no shortage of doctors in Norway.

THE ACTIVATION OF WOOD CHARCOAL.

AN important communication to the Chemical Society made recently should not escape the notice of active workers in the physiological and chemical laboratories, inasmuch as the use of charcoal as an absorptive, decolouriser, and clarifier, helps research work in so many directions. The authors, James C. Philip, Sydney Dunnill, and Olive Workman, have confirmed the observation that the absorptive power of wood charcoal is notably increased by prolonged heating, an observation which occurred in the course of investigations aiming at the improvement of defence against poison gas. Further experiments are in progress, but, so far, it has been easily established that the increase in the absorptive power of wood charcoal for gases effected by continued heating of it is paralleled by a marked increase in the power of the charcoal to remove methylene-blue from its aqueous solution. Further, animal charcoal, contrary to general belief, possesses no advantages over wood charcoal, and the activities of animal charcoal are even surpassed by a heat-treated wood charcoal. It is remarked that the decolourising power of a charcoal appears to be primarily determined by its physical structure and its surface development, and not by the presence of any specific admixture. Nitrogen and ash are ruled out as playing any part in the absorptive power of charcoal. Apart from gas absorption, a sample of vegetable charcoal was found to remove only 1 per cent. of methylene-blue from the standard solution employed, but the same charcoal heated for 20 hours at 870° C. removed no less than 45·4 per cent. of the dye. Similarly it is concluded that the efficiency of animal charcoal is a function of the heat treatment it has received, and can be increased to a very notable extent. Thus a sample of animal charcoal which removed 17·8 per cent. of methylene-blue from solution before heating, removed 69·6 per cent. after being heated for 18 hours at about 800° C. We remember in our student days the lecturer on chemistry, in demonstrating the absorptive powers of charcoal, insisted upon the incineration of cocoanut shell in a crucible filled with sand some hours before the lecture experiment. As a result he always succeeded in showing practically the complete absorption of ammonia gas. A tube over mercury was filled with ammonia gas, and then a few pellets of the freshly-prepared and heated charcoal were introduced. The mercury rose rapidly to the top of the tube, and there was practically no gas left. This property of charcoal was subsequently utilised by Sir James Dewar in the production of the high vacuum, the study of which led to results of considerable scientific importance. The remarkable activation of charcoal by the comparatively simple method indicated in these researches may well have pharmacological significance. Charcoal has long been used in gastric disturbance with eructation, the element, it was claimed, serving as an absorptive, not only of gas, but of fluid in hyperacidity. The charcoal employed for this purpose was probably in most cases stale, and it remains to be seen if applications of activated charcoal prove more effective.

EROSIVE VULVITIS

ACCORDING to Dr. Thomas Latane Driscoll,[1] of Richmond, Virginia, this condition is not generally recognised, although the corresponding disease in the male, known as erosive or gangrenous balanitis, has been known for several years. Like Vincent's angina and ulcero-membranous stomatitis, it is due to the symbiosis of the fusiform bacillus and spirillum. The predisposing causes are filth and prostitution, with attending frequent copulation and exposure to unnatural sexual relations. Dr. Driscoll reports three cases in women who were inmates of the jail at Richmond and had all been convicted of prostitution. The genitals were extremely dirty, and showed a large amount of discharge from the diseased focus and from the vagina, so that ideal conditions were present for the growth of the specific organisms. In each case there was extensive ulceration of the part, with a slight amount of local œdema. In the most severe case there was an almost complete destruction of the vulva, the labia and clitoris having completely sloughed away. In all three cases the inguinal glands were enlarged without signs of suppuration. There was a slight degree of toxæmia and the patients showed a tendency to melancholia. The Wassermann reaction was negative in all three cases. There was no response to antisyphilitic treatment, including arsphenamin. In conclusion, Dr. Driscoll states that erosive vulvitis may be suspected in the presence of persistent ulceration, with a negative Wassermann reaction and the clinical characters described above. The presence of fusiform bacilli and spirilla confirms the diagnosis, but it must not be forgotten that the infection may be superimposed upon other lesions of the genitals.

THE POSITION OF THE CITY BACTERIOLOGIST.

WE note with interest that a movement is taking place in the city of Belfast to appoint the professor of pathology and bacteriology as city bacteriologist, following the example set by Liverpool seven years ago. This arrangement, by linking up city and university more closely—an end desired by all who have the real concern of their University at heart—possesses advantages for both. The city is able to secure for its bacteriologist a man whose training, academic record, and ability in research have been tried and tested by the fact that he has secured a professorial chair. On account of his recognised standing his decisions on work submitted to him are at once accepted by the health authorities with whom he has to deal; being a professor, appointed and paid by the university, he has an independence which no purely city official can have. The university gains in being brought more closely in touch with city work and in obtaining material of enormous value in practical teaching, especially for those who are to adopt public health as a career. To take an instance specially applicable to a port like Liverpool—the control of plague by systematic rat examination. This is daily routine, and every student has an opportunity of seeing all the details, from the work carried out in the sanitary offices to the complete report by the bacteriologist, and that not once or twice, but every day if he should so wish.

Some fear that, under dual control, difficulties might arise in dealing with city councillors and health committees, by the very fact that the professor holds an independent post. Experience in Liverpool shows that these difficulties are imaginary. Cranks exist in lay or medical bodies, but, though they annoy, their influence is negative or passing. A further advantage lies in finance. In Liverpool, where the upkeep of the laboratory rests in the main on the city, the work done in it is not starved, as is the case with so many university laboratories, and will remain the case until our rulers come to realise fully that research can only be satisfactory when carried out in a well-equipped laboratory with a qualified and adequately paid staff. The Liverpool arrangement has worked well, and has fully justified the wisdom of the members of university and city who brought about the union. It has, of course, its weak points; one particularly is that pathology is not associated with the bacteriological department. Bacteriology and pathology cannot be separated with advantage, and it may be hoped that in Belfast the present connexion between the two subjects will be maintained. Should it prove necessary to divide the two departments, professors of equal status should be appointed. In any new scheme we would like to see a closer relation between clinical work and bacteriology and pathology. Both professors might be honorary officials of some hospital, infectious or otherwise, with free access to the wards and with the status of physicians. In this way only will research on the ætiology and treatment of disease be carried on with success.

CORONERS JURIES

THE inquest held recently by the Rotherhithe coroner upon the bodies of David and Ada Ayles, husband and wife, has been the subject of comment on account of Mr. W. H. Whitehouse having conducted the inquiry without a jury. The deceased were in poor circumstances, allegations were made that their deaths were due to starvation, and that a relieving officer had refused assistance which should have been afforded. On the other hand, apart from conflicting evidence given by lay witnesses as to the alleged shortage of food and money, Dr. R. C. Harkness, medical superintendent of the Bermondsey and Rotherhithe Hospital, where the luckless couple died, attributed their deaths to pneumonia, and stated that the woman was not emaciated, but fairly well nourished, and that the man, though naturally thin, did not give the impression of being starved. In the circumstances, it is difficult to see how a jury could properly have returned any other verdict than that given by the coroner, which ascribed death to natural causes. It was a case, no doubt, in which in the exercise of the discretion given him by the Juries Act, 1918, the coroner might have summoned a jury without anyone suggesting that he was shirking unduly the responsibilities of his office. It was not, however, a case in which he was bound to have a jury, for whatever the conduct of the relieving officer had been proved to be, it could not have been a question of his having committed murder or manslaughter. As to the cause of death, with which alone the coroner was concerned, the medical evidence was conclusive. Whether it is desirable to dispense with a jury in coroners' courts for cases not likely to result in charges of manslaughter is a difficult question in the light of experience recently gained; probably a jury is generally desired by the public. The matter will no doubt be made clear when a Bill to amend the law of coroners' inquests is introduced. What is not clear at the present time is why the experiment is being continued. The conditions which brought about the Juries Act of 1918, and the Coroners' Emergency Provisions Act of 1917, providing for smaller juries at inquests, are now over, and both Acts were passed to have effect during the war, and for a period of six months thereafter.

---

[1] Archives of Dermatology and Syphilis, February, 1920

ROYAL SOCIETY OF MEDICINE: SECTION OF SURGERY.

AT the annual meeting of the Section of Surgery of the Royal Society of Medicine there was a very interesting exhibition of specimens from the museums of the London hospitals illustrating innocent tumours of the alimentary tract and leather-bottle stomach. It is hoped to hold similar exhibitions from time to time. A gratifying feature of the session, now closed, has been the increase in attendance, and the thanks of the members are due to Sir John Bland-Sutton, the President, for his successful stimulation of the section.

THE WINDSOR COLLIERY INCIDENT.

WE briefly recorded last week the proposal of the employees of the Windsor Colliery at Abertridwr to become a registered society providing medical attendance. A South Wales correspondent writes that the position is much as follows:—

> In the past doctors have practised in the mining areas for as short a time as possible, desiring to make money, and, having done so, to leave the districts, which are not congenial for the permanent abode of professional men. The tendency has therefore been to undertake an excessive amount of work, obtaining for it the best scale of remuneration possible. Those who have been able to stand the work for 20 years or longer have retired on the proceeds. The proposed Medical Aid Society reduces the income of the practitioners when compared with the scale of earnings under the present method of procedure. Whether it will reduce the amount of work each man is called upon to undertake it is difficult to say. What appears to be wrong in the miners' proposal is not so much the income suggested as the number of doctors whom they propose to engage. What is wanted is more doctors, not more pay.

Our correspondent thinks that the position taken up by the medical profession has not been made very clear locally. It is stated in the *Western Mail* of May 3rd that, when the idea was first mooted, local practitioners agreed to the new procedure should it receive the sanction of the British Medical Association. The doctors who previously attended the miners and their families have now, politely but firmly, decided not to work the scheme, which, when submitted to the Association, was placed amongst the banned forms of contract practice. Nothing has been put forth to enable the miners to distinguish between the position of a whole-time medical officer of health working for the health committee of a town council, or a tuberculosis officer in charge of a sanatorium managed by a lay committee, and that which the proposed Medical Aid Society offers. The objection offered, that choice of doctor is lost, has some weight, for although under the arrangement the society intends choosing its own officers, it should be remembered that there was a 30 per cent. minority which voted against the new scheme, and which, if coerced into adopting it, will have their choice of doctor restricted against their will. The disfavour with which the Association regards contract practice in any form is based on the belief that a limitation in the scope of his practice will necessarily in the long run impair the quality of the service offered by the practitioner. The Windsor colliers should be put in possession of the evidence upon which it is based, as they would then see that their proposed society will benefit neither themselves nor the doctors.

THE PREVALENCE OF HERNIA.

THE incidence of hernia in the general population is a subject which has attracted attention for many years. The question has never been satisfactorily settled, as it has only been possible to examine, in sufficiently large numbers, special classes of the community such as school children or young military recruits. In the recent Report of the Ministry of National Service on the Physical Examination of Men of Military Age, to several aspects of which attention has already been drawn in these columns,[1] the prevalence of hernia has not been overlooked, and new and valuable data have been obtained. It is unfortunate for our present purpose that the majority of the reports give only the percentage of men relegated to Grades III. and IV. on account of hernia and not its total incidence. In two reports, however, this is done. Dr. J. D. Comrie,[2] in a series of 10,000 recruits drawn from a mixed rural and urban population in Scotland between the ages of 18 and 41, found that 3·6 per cent. were the subjects of hernia. Of the 363 cases 12 only were rejected. He states that of the cases which had been operated upon one-sixth had recurrence. It is obvious, therefore, that 3·6 per cent. does not represent the true incidence at these ages, as the cured cases are not included. That the liability to hernia increases to the end of a man's working life is shown by Dr. Basil Cook in the report of the medical officer to the Local Government Board for 1908–09, where he states that the rate per million ruptured continues to increase till the age of 65. This is borne out by the regional report for Manchester and Stockport district, where of 2994 men aged from 43 to 51 12·5 per cent. were ruptured, and by a chart showing the percentage rejections for various age-groups in the London district. Of the economic effects of hernia we can judge from the statement that of 160,545 men in the London district 1·1 per cent. had such severe forms of hernia as to be placed in Grade IV.—that is, they were judged "totally and permanently unfit for any form of military service," even of a sedentary nature. In civil life the economic value of these men must be lowered. Dr. Cook also states, in the report cited above, that of 3162 adults seen in workhouses in 1907 1·9 per cent.

---

[1] THE LANCET, March 6th, p. 557; March 27th, p. 726; April 3rd, p. 780.

See also THE LANCET, 1919, ii., 957.

attributed their pauperism to the incapacitating effects of hernia. The results of the modern operation for the cure of hernia are known to be excellent in early cases; thus in 1902 the army and navy invalided 15 per cent. and 25 per cent. respectively of their hernia cases, while in 1908, after extending the use of the operation, the rate fell to 4 per cent. in each case. It seems to us that an official inquiry might well gauge whether sufficient provision is made for operating on these cases, and whether the two causes which at present prevent men availing themselves of the existing accommodation can in any way be obviated. The causes are the length of the waiting lists at hospitals and the difficulty which a man with dependents has in giving up his work for the necessary time. The question of the provision of trusses of good patterns might also come within official purview. Many of those on the market are quite unsuitable, and the advertising quack who supplies an "appliance," with or without a substance to rub into the skin, robs the working man, in the aggregate, of many thousands of pounds a year under the pretext that he will not only retain but cure the rupture.

TO OUR READERS.

THE greatly increased and still increasing cost of paper—and, indeed, of everything connected with the making of a newspaper—has necessitated an advance in the price of THE LANCET. The rise in postage rates, also promising to go higher, is a factor working in the same direction in every newspaper office. The alternative to an advance in price—namely, a serious curtailment of the contents—would, in our opinion, abate too much of the usefulness of the journal to make it acceptable to our readers. We hope and believe that they will agree with us that at no time has it been more necessary for the profession to interchange freely their knowledge and their experiences, and to learn as fully as possible what their social and professional relations will be in the approaching period of reconstruction. We believe that we best interpret the wishes of the readers of THE LANCET by not attempting to reduce the present size of the journal, and it has accordingly been decided, with the issue of May 22nd, to increase the charge for the weekly issues of THE LANCET from 10*d.* to 1s., the inland subscription from 36*s.* to 42*s.*, and the foreign subscription from 40s. to 50s.; for the impossibility of getting thin paper for the foreign copies leads to an increased rate of postage on the copies sent abroad. These changes will not take place during the currency of present subscriptions, but will operate on their renewal. We have not made the increases without ascertaining their necessity, and we shall be delighted when circumstances permit us to return to the former prices.

THE Croonian lecture of the Royal Society on Genetic Segregation will be delivered by Professor W. Bateson at the meeting on June 17th.

WE commend to our readers a short notice, which appears in another column (p. 1085), of the existing position of the Auxiliary Royal Army Medical Corps Fund. Over £4500 were distributed last year in reply to great needs. But the needs remain, and subscriptions are urgently required to meet a great debt of honour.

A NATIONAL COLLECTION OF TYPE CULTURES.

THE Medical Research Council has long had in view the formation of a National Collection of Type Cultures, from which biologists in general and bacteriologists in particular may obtain, through a trustworthy source, authentic strains of recognised bacteria and protozoa for use in scientific work. The need of an available supply of this kind has long been felt in many directions and particularly in medical research work, for the study of principles and methods in bacteriological technique and for the systematic classification of bacteria and protozoa in the various species and strains.

Previous Provision of Facilities.

In the past the needs of workers in this respect have never been fully met. In this country the Lister Institute of Preventive Medicine has for many years assisted bacteriologists both at home and abroad, so far as the resources of its own private collection have permitted, but British workers have been dependent in great part upon the courtesy of scientific colleagues or upon the collections of institutes in other countries. Before the war the collection at the Pasteur Institute in Paris, maintained by M. Binot, was very helpful to workers here. A collection of type cultures was formerly maintained on a commercial basis by Král at Prague, and this was subsequently transferred to the Sero-physiological Institute of Vienna. This source of supply was never completely satisfactory, though many made use of it. In America the Museum of Natural History in New York has maintained a Culture Bureau during the last eight years, and it is believed that the activities of the Bureau have been of the greatest benefit to workers there, not only by the provision of authentic cultures, but also by the studies in classification made by its staff. Early in the present year the Medical Research Council was able, by the courtesy of the governing body of the Lister Institute, to make arrangements to maintain a National Collection of Type Cultures at the Institute, where all the necessary facilities have been provided. The scheme will be under the general direction, on behalf of the Council, of Dr. J. C. G. Ledingham, a member of the staff of the Lister Institute, while Dr. R. St. John Brooks and Miss M. Rhodes have been appointed by the Council to be curator and assistant curator respectively. The Medical Research Council acknowledges its indebtedness to the governing body of the Lister Institute for this opportunity of establishing a central collection upon a proper footing at once, without further delay. The present arrangement is made for a short term of years, before the end of which the future location of the collection will be considered.

Aims and Objects of the Collection.

It is proposed to collect and maintain bacterial and protozoal strains of medical, veterinary, and economic importance, but in the immediate future the efforts of the staff will be directed more particularly to obtaining fully authenticated strains of pathogenic organisms. Subsidiary researches on the viability of bacteria in artificial media will be undertaken with a view to the discovery of economical and labour-saving methods of subculture. The staff will also be prepared to give help in the identification and classification of strains received from workers at home or abroad.

The coöperation of bacteriologists is earnestly invited, and in return every effort will be made to supply the needs of applicants for cultures. Cultures that may be sent either for identification or for maintenance in the collection should be accompanied by the fullest particulars as to source and date of isolation and, if possible, by clinical and epidemiological notes. It must naturally be left to the discretion of the director to decide whether given cultures are of sufficient importance to be maintained in the collection, but it is hoped that this will not deter workers from forwarding strains of even the commonest types of organism. These will have value at least for the adequate representation of strains of recent origin. Studies in classification will also be aided if large series of authentic specimens of different but closely similar or cognate species are available for workers.

Cultures will be supplied on demand so far as possible to workers at home or abroad, and, as a rule, a small charge will be made to defray the cost of media and postage. Strains representing at least the commoner types of human infection can already be supplied, and at a later date it is proposed to prepare a catalogue for publication.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Scottish Board of Health Memoranda.

Malaria.—A memorandum issued to each local authority deals with indigenous cases of malaria occurring in Scotland. It is pointed out that there are in Scotland a large number of men who contracted malaria while on service, and the presence of individuals having the parasite in their blood cannot be overlooked. The anopheline mosquito is found in Scotland in many localities, though its activities are limited by the climatic conditions, excepting between the months of May and September. The tertian form of the disease is that most likely to be seen, and diagnosis should be easy from the typical clinical picture it presents. It should be kept in mind that children are highly susceptible to malaria, particularly those who are ill-nourished. Arrangements have been made whereby specimens of blood from suspected cases can be examined at the laboratory of the Royal College of Physicians. Malaria has recently been made notifiable in order that medical officers of health may make investigation into possible sources of infection. In an appendix mention is made of all districts in which the anopheles has been recorded to occur.

Treatment of Tuberculosis.—The Scottish Board of Health in a circular state that the village settlement idea, to which they attach great importance, is related on the one hand to the sanatorium and training colony, and on the other to the re-introduction of ex-sanatorium and training colony patients into employment. In such settlements ex-Service men would be given the opportunity of permanent employment, with housing accommodation for themselves and their families. The committee consider that such men would be more willing to enter sanatoriums and to remain there for a sufficient period if they knew that in so doing they had a definite prospect of continued treatment and training and later on care in permanent settlements. The committee believe that where schemes of "colony" training are put forward under suitable conditions, are sympathetically managed, and hold out a prospect of permanent settlement, ex-Service men will be willing to avail themselves of the opportunities offered. Such settlements should be in close connexion with existing sanatoriums and training colonies. The committee suggest the provision throughout the country of ten such settlements with accommodation in each for from 200 to 250 men and their families, and on this basis there might be one or two of these settlements in Scotland. They recommend that the Government should provide a sum of £1,000,000 to finance a number of village settlements for ex-Service men, which might be provided either by local authorities or by voluntary bodies. They further recommend that where these settlements were provided by local authorities the Government should meet the capital cost outright, but that after, say, five years the scheme would more properly form part of the local provision for the treatment of tuberculosis, and that then local authorities should repay an agreed proportion (not less than one-fifth) of the capital expenditure. The present purpose of the Board is to bring to the notice of the more important local authorities the possible establishment of village settlements, and to intimate that at an early date a conference for discussion of possible action will be held.

Small-pox in Scotland.

The continued extension of small-pox in Scotland is viewed with anxiety by the public authorities. The disease first made its appearance in Glasgow in the month of March, and since then there has been a progressive increase in the number of cases, as well as an extension of the outbreak to other districts. The origin of the present epidemic has been traced to two sources—one a ship from India and the other a ship from Egypt. In a considerable number of cases there has, however, been failure to discover the source of infection. The number of unvaccinated persons has very greatly increased of recent years, and the position is one which is favourable for the further extension of the outbreak. The type of small-pox is severe. The Scottish Board of Health has issued a circular to local authorities in which it is urged that for the present all cases of "chicken-pox" should be made notifiable, and that the necessity for immediate medical advice in any case of doubtful illness should be urged upon the public. In Glasgow it has been pointed out that the outbreak has been largely confined to unvaccinated children and to unrevaccinated adults. Of 11 deaths, 9 were in unvaccinated individuals, of whom 7 were children; no death has occurred among vaccinated children. During the fortnight ending April 17th there were 12 cases of small-pox in Scotland; for the next fortnight there were 21 cases; while for the current period ending May 15th, there have been up to date (9th) no fewer than 42 notifications. Glasgow still remains the headquarters of the disease, but cases have occurred in Edinburgh, Falkirk, and elsewhere. Every possible measure for control of the epidemic is being adopted, and the need for recent vaccination is being widely brought to public notice. The Glasgow figures to date show a mortality of 29 per cent. among the unvaccinated, and of 5 per cent. among the vaccinated.

Influenza in St. Kilda.

The isolated population of St. Kilda is at present suffering severely from influenza, and the numerous reports in the daily press have not exaggerated the proportional incidence, but have not always indicated the size of the population affected. The inhabitants number about 80, of whom at least 60 have been affected. Communication with the mainland has been very difficult since the termination of the war and the withdrawal of the wireless station and of naval patrols. News of the outbreak and of shortage of medical stores was brought to Fleetwood by a trawler. There is no medical man on the island, and care of the sick is in the hands of the district nurse and the parish minister. Immediately on receipt of the news the Board of Health dispatched one of their medical officers and a supply of stores to the island. The St. Kildans, owing to their isolated position, are said to be particularly susceptible to the ravages of epidemic diseases.

Proposed Acquisition of Oldmill Poorhouse by Ministry of Pensions.

The Ministry of Pensions propose to acquire 200 beds at Oldmill Poorhouse, Aberdeen, as a hospital for disabled ex-Service men. This poorhouse formed the 1st Scottish General Hospital during the war. For repairs necessary to the poorhouse as a result of its occupancy by the military authorities during the war the parish council claimed the sum of £18,000. As this sum is still outstanding, and as the repairs have not yet been completed, it is unlikely that the parish council will entertain the request of the military authorities until an amicable settlement as to the expenses incurred in repairing the premises has been arrived at.

Aberdeen Sick Children's Hospital.

Sir James Taggart, ex-Lord Provost of Aberdeen, has written to the local papers suggesting a plan to raise funds for the building of a new Sick Children's Hospital at Aberdeen. His suggestion is that all the workmen in the city and the surrounding district should work one Saturday afternoon in their various factories and workshops, and hand over the wages earned in that afternoon to the hospital fund, the employers also contributing their share in the scheme. Sir James Taggart calculates that, taking the number of the workers in Aberdeen to be 63,645, four hours' work at an average of 1s. per hour would realise the sum of £12,729. To this would be added the employers' contributions and the sum received from the surrounding districts. The appeal has received a mixed reception. Several employers have expressed hearty approval of the scheme, but the general feeling would appear to be that the scheme is impracticable.

University of St. Andrews.

At a meeting of the University Court of St. Andrews held on May 1st the following appointments to lectureships were made: lectureship in regional anatomy (Dundee), Dr. John Taylor; lectureship in diseases of children, Professor Ll. T. Price.

The first meeting of the General Nursing Council for Scotland was opened on May 10th, at the Scottish Board of Health, Edinburgh, by Sir Leslie Mackenzie. Captain C. B. Balfour, of Newton Don, and Miss Norah Milne, B.Sc., were appointed chairman and vice-chairman of the Council, with Mr. C. L. Farmer, of the Board of Health, interim secretary.

May 10th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Eight Hours' Day for Hospital Staffs.

NO one has doubted the difficulties accompanying the application of the eight-hour day law to hospital staffs in Paris. Before adopting the Order a careful study of the question was made by committees composed of members of the municipal council, administrative officers of the Assistance Publique, and representatives of the various unions concerned. It is obvious that the new law has resulted in a considerable increase of expenses, which cannot be accurately estimated at present, and, indeed, will not really be appreciated for a year. The arrangements adopted consist of the division of the personnel into three groups—a morning shift, an afternoon shift, and a night shift. The first two groups work respectively for 9½ hours, with an interval of 1½ hours for meals, to be taken at will outside the hospital (no rebate being allowed) or within its walls. The night shift works for eight consecutive hours, and its members are provided with breakfast before leaving hospital if desired. Since trade-unions in general have promised that shorter hours will be compensated for by more concentrated work, it has been arranged that hours of work shall be counted, not from the time that the employee enters the establishment to the time he leaves it, but from the moment of his appearance dressed for duty till that at which he leaves his post. Moreover, holidays, which have been fairly easily obtained till now, will only be granted under exceptional conditions. Too frequent sick leave will lead to dismissal. The services of employees whose work can be replaced by an extended use of the telephone, telegraph, or postal departments will be dispensed with. The attendant will have to remain actually in the wards, and will not be allowed to attend courses and lectures in the hospital during his duty hours. The three shifts will not have the same numerical composition. The morning shift, which will arrive before the visiting staff, take temperatures, attend the round, take down the prescriptions, and assist at operations, will be the most numerous. The times of arrival of attendants are scheduled from 6 in the morning to 8.30, at half-hourly intervals, the first comers leaving earlier, and the last comers leaving at 6 in the evening. Similarly the dinner hour is fixed at three successive hours, so that all the attendants in a ward will not be absent at the same time. The afternoon shift succeeds the morning shift in the same way, at half-hourly intervals, and with variable meal times. The night shift, the least numerous of the three, takes over at 10 and 11 at night, and leaves at 6 and 7 in the morning. When its members leave in the morning they indicate to the day shift all necessary information and directions as to continuation of treatment. M. Mesurier has devised a special case paper, divided into three parts, on which each shift writes notes which can be consulted at any moment by the Chief.

The principal difficulty resolves itself into the question of the meal times of the afternoon shift. Because of the variable hour, always late, at which the mid-day meal is taken, its duration has had to be limited to half an hour, as compared with an hour and a half in the case of the morning shift. M. Mesurier recommends that this shift should be recruited from attendants living in; if any externs have to be employed they should take their meals in the hospital refectory during a half hour between 1.30 and 2.30. For the general employees of the hospital not working in the wards an eight hours day has been much easier to organise, with four hours in the morning, four in the afternoon, and an interval of one and a half to two hours for dinner. In all, the personnel of the hospital has had to be increased, not by 33 per cent., as had been calculated, but by 20 to 22 per cent.

Athletic Sports at the Military Hospital.

An interesting innovation has just been established in Paris at the Hôpital Villemin. The medical officer in charge has for 10 years specialised in the differentiation of human constitutions and temperaments on an anatomical basis, and has undertaken to prove the results of his studies by practical demonstrations. Convinced that the perfect human type is that developed by Olympic exercises and by running, he has obtained the permission of the military authorities to convert into training grounds the lawns of the old hospital. Not only convalescents will be drilled there, but also soldiers from the neighbouring barracks if desired. Already the school of physical re-education at Joinville has collected together all the soldiers in bad general condition, but with no disabilities justifying their exemption from military service. All the medical officers in charge of troops have been asked to hunt out puny recruits and to send them to this school, where three months of physical culture in the fresh air are expected to transform them into strong soldiers in excellent condition for the army. The military medical service in France is thus entering a path which should lead to real progress.

VIENNA

(FROM OUR OWN CORRESPONDENT.)

Post-graduate Lectures and Clinical Courses at the University of Vienna.

THE time-table for the summer term of the Medical Faculty of the University of Vienna has just been published. It contains the announcement of 448 different classes, which will be held by 21 ordinary, 113 extraordinary professors, and 152 private teachers and clinical assistants. As the chairs of obstetrics and gynæcology, as well as experimental pharmacology and pathological anatomy, are still vacant, these subjects will be taught by the chief clinical assistants. The fees payable are for the first time in some accordance with the general rise of prices, and the students have in vain tried to induce the Government to stick to the low fees hitherto paid for clinical teaching. A student, whose lecture fees for his sixth half year used to be about 60-100 kronen, now has to pay at least 500-700 kronen, special courses not included. Post-graduate courses are still more expensive, costing now about 1000 kronen for each course. This increase of fees would not be of great moment to English or American students, however, for even 1000 kronen is at the present rate of exchange about equivalent to $5 or 25*s*. There will be 8 classes in physiology, 35 on pathological anatomy, 81 on general pathology, 22 on rhino-laryngology, 29 on otology, 46 on surgery, 41 on dermatology and syphilis, and 12 on radiology, besides numerous others on subjects of less general importance.

Increase in Number of Medical Students.

The winter session lasted from October, 1919, till March, 1920, and the figures are now available for comparison and comment. There were registered 4282 ordinary students of medicine (against 3697 the term before), amongst them 578 women. Besides these there were 221 extraordinary students, mostly foreigners, of whom 32 were women. The increase in the number of students is well marked since 1915, and the output of graduated doctors is growing so rapidly as to constitute a real problem. Already there are over 4000 practising doctors in Vienna, against 3100 in 1914, whilst the population of the capital of our mutilated country has gone down from 2,250,000 in 1914 to 1,860,000 on Dec. 31st, 1919.

Investigations on the Caloric Needs of Large Numbers.

In a paper read by Professor Durig before the Medical Society of Vienna quite recently, the results of exhaustive investigations conducted by him and his staff into the conditions prevailing among the population of Austria have been given, and serve to elucidate several problems of nutrition. First of all, it appears quite clear that the old teaching of Voit is correct, that 3000 calories are necessary for the human body to maintain its metabolism equilibrium. This was believed to be too high a figure at the beginning of the war. But it was soon proved that Voit's teaching cannot be ignored. Not every person requires 3000 calories—only men of 70 kilos. weight doing moderate labour. If large numbers are to be cared for one must calculate with provision-units or food-units. Thus, for example, 100 females are equal to 80 units, and 100 16-year-old adolescents are equal to 65 units. The figures of the last Census of 1910 show that in pre-war times 100 persons of the population of Old Austria required 77 units of provision or food, and this amounts to 2200 calories. This figure coincides very closely with the 2300 calories postulated by Professor Rubner as the average requirement in his famous researches on German people during the first months of the blockade of his country. At present our population has changed so much that the proportion of males to females is 100 : 120; previously it was 100 : 103. There are now fewer children and old-aged people. The average body weight, which stood in 1913 at 46 kilos., is now 41 kilos. The hours of work are less; formerly 9–10 per day—now hardly 8 hours, and the intensity of work has decreased. Therefore the caloric requirements have gone down at least 10 per cent. And as there is hardly any matter wasted in our foodstuffs now—everything is being utilised by our hungry people—the caloric requirement is at present about 1700, which must be provided for if catastrophe is to be avoided. Rationing of food has serious drawbacks, as the uniform ratio of the caloric value guaranteed to each citizen by the present method of food distribution is insufficient even for a widow with young children, without mentioning a hard-working labourer, who may need over 4000 calories a day. Professor Durig earnestly recommends improved methods of agriculture as the only means to obtain adequate quantities of food in our country without resorting to the ruinous import of cereals from abroad.

Health Statistics for the First Quarter of 1920 and Before.

The chief medical officer of health for Vienna has recently made public a few statistical items which are not without interest. In the first weeks of the year the mortality was about 740 cases per week; in the second week of February it rose to 1030, owing chiefly to influenza and heart disease, and continued to rise to 1045 and 1106. Whilst tuberculosis has claimed nearly the same number of victims every week, the figures vary between 157 and 163 per week. Nearly as many have fallen victims to influenza after a temporary drop in January. On an average the mortality corresponds to the general conditions of nutrition and work prevailing in this city. Graver affections of the heart and the circulatory system often prove fatal because of diminished resistance of the body. Death due to heart disease is becoming more frequent. Measles and scarlet fever have been rather virulent; over 40 deaths per week were caused by these diseases. The average daily number of deaths was 125. In the years 1911 to 1916 the total number of deaths ranged between 33,500 and 37,600; this number rose in 1917 to 76,131, and in 1918 to 51,497, but dropped in 1919 to 49,932. Although the population also diminished in 1919—it is now 20 per cent. less than in 1914—the death-rate has not kept pace with it. The birth-rate in the years 1911 to 1914 was between 36,000 and 38,000. In 1915 it fell to 29,575, and the next year it was 23,491. In 1917 it dropped to 20,688, in 1918 to 19,287, whilst 1919 showed an increase to 24,128.

April 22nd.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Medical Education.

SOME time ago the Melbourne University left the insistence on Latin and geometry as compulsory subjects for matriculation, before entering on a medical course, to the discretion of the Medical Faculty in individual cases. At the last meeting of the Council it was decided to abolish them as compulsory subjects altogether. This was opposed by Sir Harry Allen, the Dean of the Medical Faculty, who said the general education of students in English was very poor, especially in spelling. The change has been made largely by the advocacy of the heads of public and private schools. Two medical members of Council voted with the majority.

The Dispute with Lodges in Victoria.

At the suggestion of the Premier of Victoria a conference was arranged between the Victorian Branch of the British Medical Association and the Friendly Societies' delegates to try to find some middle way in respect of points which still separate the two parties to a dispute which has remained unsettled for two years. After Judge Wasley, had, as arbitrator, awarded practically the terms the B.M.A. were asking nothing further was done, because the B.M.A. insisted on medical institutes which had been started since the dispute began being closed. To this the Friendly Societies would not agree, and a deadlock ensued which the societies tried to overcome by sending a representative to England to engage new medical officers for further institutes. This course is only approved by some of the extremists, and the conference took place, with the result that three of the large Orders have agreed to accept the following terms as a basis if approved by their annual meetings, to be held in March. It is possible that a satisfactory arrangement will be reached, though the M.U.I.O.O.F. and a considerable section of the A.N.A., two of the largest Orders, are opposed to any compromise. The provisions are:—

1. Acceptance and recognition of the terms of the Wasley award.
2. The exercise of freedom of choice to members of the Friendly Societies selecting their doctors.
3. No victimisation or undue influence to be exercised by either parties to the present dispute.
4. No interference with the staffs or conduct of present established institutes.
5. An undertaking by the Friendly Societies that the respective governing bodies will submit to their annual conferences (with a strong recommendation for adoption) a rule prohibiting any branch or body of members taking part in the establishment of a new institute for four years.
6. The governing bodies of the various Orders will obtain control of all medical arrangements of individual lodges. (The Australian Natives' Association and the Independent Order of Rechabites have taken the necessary steps and secured control. The United Ancient Order of Druids will submit alteration of rules at next annual meeting.)
7. That all arrangements with medical officers shall be made with these governing bodies.
8. Machinery will be devised to enable the societies to carry out their promise of free choice of doctors.
9. There be appointed a committee representing the Victorian branch of the British Medical Association and the Order or Orders for the purpose of carrying out the terms of the agreement, and to interpret the meaning of any clause or condition contained therein.

Tasmanian Health Legislation

A new Hospitals Act came into force last year it provides, inter alia, for the inspection of hospitals by the Chief Health Officer and the control of persons suffering from infectious disease The notification of venereal disease does not appear to be a very satisfactory measure For the year 254 males and 53 females were reported suffering from gonorrhœa and 36 and 17 respectively from syphilis It is obvious that these figures must be inaccurate and that female cases especially are not being returned

Death of Sir T Anderson Stuart

The death is announced of Sir Thomas Anderson Stuart, M D , who came to Sydney some thirty years ago to found the Medical School in the Sydney University His work has been crowned with the most gratifying success and his many students have always had an affection and esteem for their Dean, who was also Professor of Physiology, which continued to his death The late Professor Stuart was a man of marked personality and made his influence felt outside University affairs Some time ago an illness began to manifest itself which in its progress revealed its malignant character Notwithstanding this knowledge and the fact that there was considerable personal suffering Professor Stuart quietly continued at his work, and at the time of his death was arranging matters for the annual opening of the school He was 63 years of age and was a well known graduate of Edinburgh University Expressions of regret have been universal throughout Australia

March 15th

The Services.

ROYAL NAVAL MEDICAL SERVICE

Temp Surg Lieut J T Wood (D) R N V R transferred to permanent list of Surgeon Lieutenants (D)

Surg Rear Admiral Sir P B Handyside placed on retired list

ARMY MEDICAL SERVICE

Col J D Ferguson is placed on half pay

Temp Col Sir A W Mayo Robson (Major R A M C T F) relinquishes his temporary commission on re posting

ROYAL ARMY MEDICAL CORPS

Temp Capt W E R Dimond and C L Spackman relinquish the acting rank of Major

Officers relinquishing their commissions —Temp Major C L Williams (retains the rank of Major) Temp Capt (acting Major) M Fitzmaurice Kelly (granted the rank of Major) Temporary Captains retaining the rank of Captain R Lawrence T Wylie, L O Weinman, D Miller M D'Albon, W L G Davies, J McGarrity

SPECIAL RESERVE OF OFFICERS

Capts R P Starkie and J Purdie relinquish the acting rank of Major

Capt J Lanigan relinquishes his commission and retains the rank of Captain

TERRITORIAL FORCE

Major C J Martin to be acting Lieutenant Colonel whilst specially employed

Officers relinquishing their commissions —Capts C E H Milner, G B Buchanan A Cambell (granted the rank of Major) and T W H Downes (retains the rank of Captain)

ROYAL AIR FORCE

Squadron Leader A Grant is granted a permanent commission as Squadron Leader

Capt A W P Pirie and Lieut F L Sergeant are transferred to the unemployed list

Capt (acting Major) A A Atkinson (R A M C , S R) relinquishes his commission on account of ill health caused by wounds and is permitted to retain the rank of Major

Capt C P V MacCormack relinquishes his commission on account of ill health caused by wounds and is permitted to retain his rank

TERRITORIAL DECORATION

The King has conferred the Territorial Decoration upon the undermentioned officers Lieut Col A G Hamilton (attached Welsh Border Mounted Brigade, Field Ambulance) Majors D C L Orton (attached Welsh Mounted Brigade Field Ambulance) V Graham (attached 5th Battalion Yorkshire Light Infantry), G P Chappel (attached 7th Battalion, Middlesex Regiment)

INDIAN MEDICAL SERVICE

Major R H Bott to be temporary Lieutenant Colonel

Col H Fooks is retired

AUXILIARY ROYAL ARMY MEDICAL CORPS FUND

The annual meeting of this fund was held at 11 Chandos street Cavendish square, W , on April 30th with General Sir John Goodwin in the chair Since the last annual meeting £1974 have been granted to help the maintenance of the orphans of 31 officers in the Auxiliary Royal Army Medical Corps who lost their lives as a result of the war, and £2620 have been granted in the same way to the orphans of 83 of the rank and file making a total of £4594 granted and 114 cases relieved in a single year As frequently several children of a single case were relieved, it will be seen that the total number of persons relieved was considerable The major part of the income of the fund is derived from subscriptions and the committee earnestly hope that these will continue to be sent to the honorary secretary Sir William Hale White at the above address

URBAN VITAL STATISTICS

(Week ended May 8th, 1920)

English and Welsh Towns —In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had declined from 18 7 to 14 2 in the six preceding weeks further fell to 13 8 per 1000 In London with a population of nearly 4½ million persons the annual death rate was 13 0 or 0 7 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 4 3 in Eastbourne 5 6 in Southend on Sea and 6 1 in Hornsey to 21 3 in Sunderland 23 2 in Stockton on Tees and 26 3 in West Hartlepool The principal epidemic diseases caused 373 deaths, which corresponded to an annual rate of 1 1 per 1000, and comprised 139 from measles, 78 from infantile diarrhœa 67 each from whooping cough and diphtheria 18 from scarlet fever, and 4 from enteric fever Measles caused a death rate of 1 6 in St Helens 1 7 in Acton and in Lincoln 2 1 in Rhondda and 2 2 in Norwich The deaths from influenza which had declined from 392 to 202 in the six preceding weeks, were 201, and included 31 in London 26 in Sheffield 12 in Bolton, 11 in Newcastle on Tyne and 10 in Huddersfield There were 1947 cases of diphtheria 1794 of scarlet fever, and 11 of small pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital against 1951 1831 and 12 respectively at the end of the previous week The causes of 43 of the 4703 deaths in the 96 towns were uncertified of which 11 were registered in Birmingham 4 in Liverpool and 3 each in London and Southport

Scotch Towns —In the 16 largest Scotch towns with an aggregate population estimated at nearly 2½ million persons the annual rate of mortality, which had been 18 9 19 2 and 18 3 in the three preceding weeks slightly rose to 18 4 per 1000 The 428 deaths in Glasgow corresponded to an annual rate of 20 1 per 1000 and included 22 from influenza 18 from measles 5 from diphtheria 4 from whooping cough 2 from infantile diarrhœa and 1 from small pox The 104 deaths in Edinburgh were equal to a rate of 15 9 per 1000 and included 3 each from measles and infantile diarrhœa

Irish Towns —The 182 deaths in Dublin corresponded to an annual rate of 22 9 or 4 1 per 1000 below that recorded in the previous week and included 14 from whooping cough, 9 from infantile diarrhœa 4 from measles 3 from influenza and 1 from diphtheria The 168 deaths in Belfast were equal to a rate of 21 2 per 1000 and included 9 from influenza 4 from infantile diarrhœa 2 each from scarlet fever and whooping cough and 1 each from enteric fever and diphtheria

ON May 8th a number of matrons and nurses, headed by Miss Mildred Heather Bigg R R C presented to Mrs Bedford Fenwick an address of thanks for her work for the organisation and higher education of nurses

MEDICAL MEN AND FRIENDLY SOCIETIES —At the recent annual conference of members of the Rechabite Society held at Exeter it was reported that it would be necessary to raise a 'big levy to meet the medical charges One member stated that many doctors were out to smash the juvenile branches of the Friendly Societies, another remarked that he did not believe this but that the medical men wanted full value for their services

Correspondence.

"Audi alteram partem."

THE HIGHER FUNGI IN RELATION TO HUMAN PATHOLOGY.

To the Editor of THE LANCET.

SIR,—In studying the series of Milroy lectures, by Dr. A. Castellani, in recent numbers of THE LANCET, I have been struck by the classification of the fungi which is therein adopted. The recognition of the sugar reactions as the sole means of separating or identifying such organisms as the yeasts, which are otherwise morphologically identical, appears to me unjustifiable at the present moment. The fermentation of the commoner carbohydrates employed in laboratories, such as glucose, mannite, maltose, saccharose, and lactose, forms an extremely unstable foundation upon which to base any classification of bacilli, or yeast-like organisms; they are regarded by most bacteriologists in the nature solely of confirmatory tests.

It is a matter of common knowledge that such a well-known organism as *B. paratyphosus* A varies considerably in its powers of fermentation of glucose, some strains producing acid only, while others produce acid as well as gas. The confusion which has arisen out of attempts to classify organisms of the Flexner group in this manner has been a source of considerable anxiety to those who are attempting to simplify the problem of bacillary dysentery. But confusion becomes worse confounded when dealing with gas-forming organisms of the *B. coli* group, which are extremely unreliable in this respect and whose reactions do not remain constant after long subculture, call them *asiaticus*, *pseudoasiaticus*, *pseudocoli*, or what you like. The same rule holds good, only more forcibly so, when one attempts to classify yeasts belonging to the genus *Monilia* in this manner. I can claim with some justification that this cannot be done, and should one conscientiously apply every test and not endeavour to create new species one will find that the carbohydrate reactions of these organisms vary from day to day, depending upon the length of incubation, length of subculture, and so on.

Considering these facts it must be conceded that Dr. Castellani has been particularly fortunate in being able to identify and name such a number of species upon such slender evidence, for one must remember that no two authors are yet agreed upon the proper reactions which such a common yeast as the thrush fungus, *Monilia albicans*, should give. In my work upon sprue in Ceylon in 1912 and 1913[1] I isolated 106 strains of yeasts, mostly from cases of sprue, and had I then had the scientific temerity, which I fortunately had not, or been able to employ a big enough series of sugars, I would no doubt have been able to name 106 new species.

It seems to me, Sir, that what is wanted at present is an attempt to simplify, not to complicate or confuse, the nomenclature of tropical medicine; the essence of science is simplicity, not complexity. The needless multiplication of names and species is most galling and perplexing to the sincere student. By these means we are descending into a veritable terminological morass, and are departing as far from Koch's postulates as it is possible to get. The cry of the student of tropical medicine is for facts, not names, and the practical application of these facts to the cure of disease.

After a due consideration of the views set forth above if we attempt to apply the reactions of these yeasts to the identification of different sugars in the urine, it appears that the inferences drawn are unwarrantable. There is only one sugar which it is important to detect in the urine, and that is glucose; and, further, the usual tests suffice; but even were the yeast test as described so accurate as to be specific, has it any practical application, and, if so, are we to understand that the tropical practitioner of the future is to carry round with him cultures of *Monilia balcanica*, *M. krusei*, and *M. tropicalis* with which to inoculate catheter specimens of urine in sterilised tubes in his improvised laboratory; and what is he to do now that the former strain has been destroyed by fire?

Finally, on the supposition that the classification and recognition of these so-called pathogenic fungi is in such an indefinite state, is it not a little premature to describe so many new diseases of the intestine, respiratory tract, cerebrum, genito-urinary system, and skin as being due to their agency? One would imagine that much investigation is required on this subject before finally accepting their existence as definite clinical entities in man.

I am, Sir, yours faithfully,
PHILIP MANSON-BAHR.

Weymouth-street, W., May 5th, 1920.

THE SURGICAL TREATMENT OF UTERINE AND VAGINAL PROLAPSE.

To the Editor of THE LANCET.

SIR,—Dr. W. Blair Bell, in his lecture on the above subject, which appears in your issue for May 8th, pays no attention to the musculature occluding the pelvic outlet; and in his surgical treatment limits himself for the most part to visceral structures, as though this musculature did not exist and is not concerned with the genesis of prolapse. This idea is supported by his reference to the prophylaxis of prolapse—a condition "almost invariably a sequel of parturition"—for the only predisposing condition he mentions is a puerperal retroflexion of the womb. Thus, we may suppose (1) that the babe passes by the musculature referred to, without affecting it, or that the muscular injury is immaterial (perineorrhaphy sufficing to deal with it); (2) that prolapse is not a hernia; and (3) that if Gilliam's operation were performed as a routine in the puerperal state, prolapse would (almost invariably) be prevented. The untenableness of this position is, I think, shown by the interval of time which usually elapses between the last parturition and the occurrence of prolapse. Cases do occur soon after labour (within a few weeks), but in the majority the interval is usually many years. Dr. Blair Bell does not indicate the percentage of these early or acute cases in his series, and I wish he had; nor does he say whether any particular procedure is necessary for their cure. This is unfortunate, for they are important from the point of view of testing operative procedures. Moreover, the occurrence of "congenital prolapse" shows that the influence of pregnancy and labour is unnecessary. Dr. Blair Bell objects to this term being applied to that prolapse which occurs within the first few days of life, and thinks it should be limited to the appearance of the cervix at the vulva (or beyond) in the young virgin adolescent, cases of elongation of the portio being excluded. Against this view we have "congenital prolapse" occurring, not only in the young adolescent, but in older virgins. Further, he does not show reason why this condition should be considered congenital, merely stating it "is no doubt due to inherent defects of the pelvic floor." But this pelvic floor is for him apparently a visceral structure, and in line with this the only way he has been able to treat these cases—the despair of surgeons—with success is by his extensive visceral procedure.

Unfortunately, Dr. Blair Bell, in his lecture, was unable to deal with the genesis of prolapse—the whole of prolapse cannot be treated in one lecture. But unless we have clear ideas of the genesis of a disease, its treatment is bound to be empirical. That confusion obtains and the surgical treatment of prolapse is empirical is shown by the lecturer's references to the opinion and practice of other surgeons; and largely explains his statement that "many cases can be cured by almost any method." Nor do I think Dr. Blair Bell's position impregnable. For if retroflexion or retroversion predisposes to prolapse, how is it these conditions are so often found without prolapse, and without the signs and symptoms of impending prolapse? How can prolapse of the vagina occur without depression of the superjacent organs? Yet we read that primary prolapse of the vagina occurs, whilst the uterus retains its normal position! How, if prolapse of the vagina causes elongation of the supravaginal cervix, is the body of the uterus retained in the pelvis? And how, in cases in which no vaginal prolapse precedes the elongation (e g., in "congenital prolapse"), is the elongation of the supravaginal cervix caused? Is it simply from traction of the cervix? All these difficult questions are resolved by the recognition *that prolapse is a hernia, that parts of the viscera* are expressed from some cavity, through some aperture or ring in a limiting wall of that cavity, *by a force or* series of forces arising within the cavity. From this we see at once that the compression or constriction exerted by the hernial ring upon the mass extruded at the region of the ring is not only the cause of the retention within the cavity (pelvis) of viscera, partly extruded (e g., body of uterus), but is also the cause of the visceral elongation in the region of the ring. Dr Blair Bell, however, paints no such picture, yet his concerted visceral procedures cure prolapse—and in 99 per cent of cases! How is this to be explained? Perhaps it is partly explained by the persistence of the limiting wall or floor in his cases—the unobtrusive musculature—and by the changes which may occur in it with the rest in bed, &c. The statement that many cases get well whatever the operative treatment rather points to some unseen agent at work. Yet cases remain in which this can be excluded, cases, for instance, which after operation by one surgeon and without an intervening parturition have soon relapsed, but have been followed by success with a more extended and complete visceral procedure And one readily admits that such visceral procedures do much, perhaps untold, good But how do they act?

---

[1] Report on Researches on Sprue in Ceylon, pp. 143–145.

If, on the examination table, after replacing a prolapsed mass, one could, by a wave of the hand, convert the easily deformable tissues into a rigid mass, no return of the prolapse, even on the greatest bearing down, could occur. On the other hand, even in the normal, if the pelvic visceral tissues possessed the physical properties of discrete grains of sand, retention during activity would be impossible. The plastic operations on the viscera have the effect of increasing the viscosity of the visceral parts concerned, which serves itself to prevent their extrusion—rather participates in doing so. How else do colporrhaphies and the other operations mentioned, and especially the interposition operation, act? To suppose they act by restoring visceral ligaments which have been stretched by the prolapse, is absurd We cannot believe that colporrhaphies affect the ligaments. That colporrhaphies do not suffice in all cases Dr. Blair Bell has shown. Nor can we believe that Gilliam's operation suspends the uterus Dr. Blair Bell depicts a uterus greatly elongated after ventrifixation done for prolapse. If the uterus will stretch after its fundus has been fixed to the abdominal wall, we cannot believe that if Gilliam's operation had been done in a similar case that the uterus would have remained in its normal position. But in such a case Dr. Blair Bell does not merely perform Gilliam's operation, he operates on the utero sacral ligaments and now occludes Douglas's pouch But we cannot believe that this "reconstruction" of the utero sacral ligament cures the prolapse; for even if it maintained the cervix behind, it would not cure the cystocele For this the perineum must still be repaired and a colporrhaphy done. Surely these concerted procedures increase *the viscosity (or diminish the deformability)* of the visceral mass in the pelvis, and give a chance to the musculature beneath to carry on These operations are performed before the menopause, when the patient is in fairly good health, before the decline which later sets in. Since in many of these patients the prolapse only appeared some time, often many years, after the last child was born, it is plain the musculature, which had been able to carry on, can do so again.

Nor is it probable that the interposition operation cures prolapse by affecting the ligaments This operation, which, as Dr. Blair Bell insists, is only applicable after or near the menopause, has been very largely practised in America; and it is surprising it has not been employed more in this country. Dr. Watkins, to whose work I believe the operation largely holds its place across the water, in a private letter (dated June 23rd, 1919) writes: "My experience has been that all men who have sufficiently tested the transposition operation have become enthusiasts, and that criticism has been offered only by men who have not done the operation." But in one of his papers, Watkins attributes the action *of the operation to the effect it has of twisting the broad* ligaments By being twisted, these become shorter. and so are able to support the uterus. I cannot accept this explanation. Does not the interposition operation—or the transposition operation, as Watkins calls it—act by increasing the viscosity of part of the visceral mass, especially that part related to the pelvic floor aperture I believe it does, and I believe that is why it is so successful in curing prolapse, and especially cystocele. The only doubt in my mind about the use of the body of the uterus in this way, is the question of its freedom from disease, and whether it will remain in a healthy state It astonishes me that sepsis should so often have complicated this operation. I have only done it twice, and on the first occasion it seemed to me the simplest operation in surgery. In the second case, that of a very stout woman, in whom I was unable to map out the uterus bimanually even with the patient anæsthetised, I had difficulty in delivering the fundus and then found to my surprise a fibroid the size of a pigeon's egg occupying the left half of the fundus. I excised this, and removed two or three other quite small fibroids, and completed the operation. In both patients the wounds healed without any sepsis whatever. Dr. Blair Bell's experience with his 50 cases is similar. But I wonder what will happen in my second case, if any further seedling fibroids develop, and how difficult it would be to remove an interposed uterus if malignant disease supervened.

These considerations make me think that in spite of the excellent results achieved by Dr. Blair Bell's operative work, we have not yet reached the zenith of the operative treatment of prolapse Something yet remains to be done, but that can only be done when clear ideas obtain as to the nature of prolapse, and the causes which predispose to it are clear to the eye

I am, Sir, yours faithfully,

Rugby May 8th 1920 R. H. PARAMORE. F.R.C S Eng

To the Editor of THE LANCET.

SIR,—In THE LANCET of May 8th, p 994, Dr Blair Bell in his lecture on this subject makes two quotations from me, and says that "readers must draw their own conclusions," adding that one of the quotations viewed in the light of the other seems to him "more than illogical." I think he does not realise that there can be retroversion without prolapse, though not prolapsus uteri without retroversion To use a parable, you can bend without sitting down, though you cannot sit down without bending Moreover, you can get up again without straightening, and the patient can often be cured of prolapse without correction of the retroversion. I learnt this from Moritz, who investigated some couple of hundred cases three years and more after vaginal operations for prolapse, and found that sometimes the patient said she was completely cured, although on examination the uterus was found to remain retroverted The operation had converted these cases of prolapse into retroversions without symptoms. In such cases why open the abdomen merely to correct the retroversion, which is doing no harm?

I was foolish enough to read 113 papers on genital prolapse published in 1918. They were all quite unnecessary, and most of them described more or less new and elaborate technical devices The writers did not appear to know that the results to which they aspired could be secured more easily, and safely by methods which had already been published *ad nauseam*.

I am, Sir, yours faithfully,

Manchester, May 9th 1920 W. E. FOTHERGILL.

STERILISATION OF MILK BY ELECTRICITY.

To the Editor of THE LANCET.

SIR,—In the annotation under this title in your issue of this date there are one or two slight errors which in fairness to others I must ask you to contradict. The work was being done in the Thompson Yates Laboratories when I was appointed to Liverpool. I did not initiate the work, but at the request of the Health Committee of the city I reported on what had been done, suggested further experiments, and in conjunction with Mr. F. C. Lewis, who had carried out the original work, made various alterations in apparatus and methods. Throughout the work Mr. Lewis has been intimately associated with me, and the reports published are joint reports. I feel that it is unfair that credit should be given to me for work which could not have been undertaken and which certainly would never have been brought to a successful issue had I not had the valuable assistance and hearty coöperation of Mr. Lewis.

I am, Sir, yours faithfully,

University of Liverpool, May 8th, 1920. J. M. BEATTIE.

LICE AS A CAUSE OF RINGWORM.

To the Editor of THE LANCET.

SIR,—The letter of Dr. A. E. L. Wear in your issue of May 1st, on the relationship of lice to ringworm, reminds me of an occurrence which happened nigh 40 years ago. On that occasion a patient showed me her forearm, on which there was a well-marked circle of ringworm about the size of a threepenny-piece. When told the nature of the ailment, she asked if it could have been brought to her by a flea, for some four days previously, when serving in her shop, she felt herself bitten at the exact spot at which the ringworm had appeared, but not caring to ascertain at the moment what had taken place, had contented herself with rubbing the part smartly through her sleeve. When the customer had gone, she had turned up her cuff, and "out sprung the flea." I told her that there could be little doubt the flea had brought the disease, and that the vigorous rubbing had implanted it at the bitten part. I made a note of the matter as a curiosity, but failed to grasp its significance, although the fact and its explanation were alike offered to me.

I am, Sir, yours faithfully,

J. ALLAN GRAY, M.A., M.D., F.R.C.P. Edin.

Leith, May 3rd, 1920.

THE DEATH OF DR. A. P. SPELMAN: A MOVING APPEAL.

To the Editor of THE LANCET.

SIR,—I take the liberty of appealing to you on behalf of the widow and children of the late Dr. A. P. Spelman, of Dunmore, Co. Galway. Last week, when returning from a call, his motor-car skidded at a badly protected part of the road, and, overturning, killed him instantly. The deceased was only 26 years of age, and had not his life insured in any way.

Mrs. Spelman and two young children are now left absolutely destitute and totally unprovided for, and in these circumstances I would appeal to your readers for their help.

Thanking you in anticipation,

I am, Sir, yours faithfully,

P. J. DELANEY, M.B.

Claremorris, Co. Mayo, May 4th, 1920.

PS.—We are circularising all the local doctors. Subscriptions, which will be duly acknowledged, may be sent to myself or Dr. T. A. Heneghan, Ballindine, Co. Mayo.

LYME REGIS COTTAGE HOSPITAL.—It is proposed to erect a new cottage hospital at Lyme Regis. The building will contain accommodation for six male and six female patients. There will also be a children's ward, two private wards, operating theatre, and an X ray room. The site has been purchased, the plans prepared, and the chairman of the hospital has issued a strong appeal for financial support.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—G. S. Ashby (Sect. I.), King's Coll. Hosp.; C. C. Bennett (Sect. I.), Guy's Hosp.; A. G. L. Brown (Sects. I. and II.), Westminster Hosp.; A. Furniss (Sect. II.), Manchester; M. Ibrahim (Sects. I. and II.), *Middlesex Hosp.; and* A. L. Urquhart (Sects. I. and II.), Edinburgh.

Medicine.—R. E. Laurent (Sect. I.), Westminster Hosp.; M. Pigott (Sects. I. and II.), Manchester; and A. L. Urquhart (Sects. I. and II.), Edinburgh.

Forensic Medicine.—E. Brazao, Middlesex Hosp.; J. A. Cohen, King's Coll. Hosp.; M. Pigott, Manchester; and A. L. Urquhart, Edinburgh.

Midwifery.—E. Brazao, Middlesex Hosp.; J. A. Cohen, King's Coll. Hosp.; A. McKenzie, Guy's Hosp.; M. Pigott, Manchester; R. M. Rodriguez, Barcelona; W. H. Summerskill, Guy's Hosp.; and A. L. Urquhart, Edinburgh.

The Diploma of the Society was granted to the following candidates *entitling them to practise medicine*, surgery, and midwifery:—M. Ibrahim, M. Pigott, and A. L. Urquhart.

THE WHITSUN CONGRÈS DE MÉDECINE AT BRUSSELS.—The Association of French-speaking Doctors is holding its fourteenth congress from Wednesday, May 19th, to Saturday, the 22nd, in the Palais des Académies at Brussels, under the presidency of Dr. Henrijean, professor of medicine at Liége, with whom are associated Professor Bordet and Professor Vandervelde (vice-presidents), and Professor René Verhoogen (secretary-general). The opening ceremony takes place on Wednesday at 4 P.M. The morning sessions commence at 9 A.M. on each following day, being devoted to (Thursday) Cardio-vascular Syphilis, (Friday) the Lipoids in Pathology, and (Saturday) the Therapeutic Value of Artificial Pneumothorax. The afternoon sessions at 4 P.M. are devoted to more general topics, such as the Social Campaign Against Syphilis, the Coagulation of the Blood, and Heredity. On Sunday an excursion to the Yser front and the Flanders coast is in prospect. Further information from the secretary-general, 22 rue Joseph II., Brussels.

UNIVERSITY OF MANCHESTER APPEAL: "THE KING'S SEVENTY."—The fertility of ideas and seductive processes evolved to bring grist to the educational mill of the University of Manchester bring also new surprises almost daily. The latest proposal is that 70 towns or districts or firms should be found, each of which should undertake to raise £5000 to swell the fund and crown the £500,000 required. These to be called "The King's Seventy." The idea has taken root and already two shoots have appeared. The Mayor of Blackpool has intimated to H.M. the King that Blackpool will raise £5000 and Crompton, a much smaller urban district, has intimated that it also will guarantee to raise an equal sum. The star on the barometer-ladder outside the University now stands at £184,000. The *Manchester Guardian* on May 7th issued an interesting illustrated supplement in aid of the same object. It contains, amongst other matters, a message from the Chancellor, Viscount Morley, who says: "It [a good university] is one of the keys and clues for that progress towards making a democracy from which there is nothing to fear and everything to hope." Viscount Haldane discourses on "The Mission of the Civic University," Sir Henry A. Miers on "The University and the Community," and Viscount Bryce on "The Function of a Modern University."

VENEREAL DISEASE CLINICS AND PROFESSIONAL SECRECY.—A deputation from the London and Counties Medical Protection Society, Ltd., was received by Dr. Addison at the Ministry of Health on May 6th. The deputation was introduced to the Minister of Health by Lieutenant-Colonel F. E. Fremantle, M.P., and the chairman of the London and Counties Medical Protection Society (Dr. C. M. Fegen), on behalf of the deputation, urged upon the Minister of Health the necessity for early legislation to protect the medical officers of venereal disease clinics from being compelled in the witness-box to violate the established principles of professional secrecy, and to give information of the nature of their patients' ailments and of anything else which came to their knowledge in their professional capacity. The medical officers of venereal clinics, he said, were being compelled in the law courts, under penalty of imprisonment for contempt of court, to reveal what their patients had communicated to them, believing that the information would be treated as absolutely confidential. The effect of this, it was pointed out, would be disastrous to the working of the venereal disease clinics, and would militate with fatal effect against the present efforts being made to cure and eliminate venereal disease. The Minister of Health expressed his cordial agreement with the views of the deputation, and promised to do what he could to promote legislation as suggested by the deputation. He said that he felt sure that public opinion would support the maintenance of professional secrecy in connexion with venereal disease clinics.

ROYAL SOCIETY OF MEDICINE. WHITSUNTIDE HOLIDAYS —The Society's house will be closed from Saturday, May 22nd, to Tuesday, May 25th, both days inclusive

THE Silver Médaille de la Reconnaissance Française has been awarded to Sir StClair Thomson for his valuable services in laryngology

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS —A general meeting of this society will be held at 122, Harley street, W, at 4 P M, on Monday, May 17th

CHELSEA CLINICAL SOCIETY.—The annual general meeting of this society will be held on Tuesday, May 18th, at 8 30 P M, at St George's Hospital Medical School

A MATINEE in aid of the Nurses' Home Fund of the Great Northern Central Hospital will be held at the Palladium to day (Friday)

Sir Thomas Horder will address the League of Youth on Tuesday, May 18th, at 8 30 P M, in Committee Room B, Central Hall, Westminster, taking as his subject Physical Welfare of the Young a National Duty Captain W E Elliot, M P, presides

Dr. J. S Fraser, of Edinburgh, will give a lantern demonstration of his micro photographic slides illustrating Diseases of the Internal Ear at the Central London Throat and Ear Hospital, Gray's Inn road, on Thursday, May 20th, at 5 P M

GRESHAM COLLEGE —Four lectures, illustrated by lantern slides, on the Vegetable Parasites Affecting Man, and the Diseases Caused by Them, will be delivered by Sir Robert Armstrong-Jones, at Gresham College, Basinghall street, London, E C, on May 18th, 19th, 20th, and 21st, at 6 P M Admission is free to men and women

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—A meeting of tuberculosis officers will be held at 1, Upper Montague street, Russell square, London, W C, on Friday, May 28th, at 3 P M, under the presidency of Dr. F N Kay Menzies, for the purpose of forming a Tubercle Group within the Society of Medical Officers of Health All tuberculosis officers are invited to attend, even if not members of the society

HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET —SPECIAL POST GRADUATE COURSES —Mr A T Pitts will give four lectures on the Pathology, Results, and Treatment of Dental Sepsis in Children, on Wednesdays, at 4 P M, beginning on May 19th, in the out patient department Other courses of special instruction for post graduates in "Diseases of Children," now in progress at this hospital, include lectures on Disorders of the Ductless Glands in Childhood, by Dr F Langmead, the Development and Care of the Healthy Child, by Dr R S Frew, on Mondays and Wednesdays, at 4 P M, beginning on May 3rd (these lectures will be held in the out patient department), Deformities of Childhood, by Mr H A T Fairbank, Tuberculosis of Bones and Joints, by Mr O L Addison, and Methods and Significance of Pathological Investigations, by Dr D N Nabarro The lectures, unless otherwise indicated, are illustrated by cases, specimens, and radiograms Tickets of admission to each group—price £1 1s —may be obtained from the secretary at the hospital The lectures in pathology will be repeated during the months of June and July, and will be held in the Pathological Laboratory

BRITISH ORTHOPÆDIC ASSOCIATION.—A special meeting will be held in Edinburgh on June 4th and 5th, under the presidency of Sir Robert Jones The session on June 4th will be held in the systematic surgery class room, Edinburgh University In the morning a discussion on the Principles of the Correction of Congenital Talipes Equino varus and Particularly of Inveterate and Relapsed Cases will be opened by Mr. R C Elmslie Mr John Fraser will speak on the Results of Tendon Transplantation for Paralyses of the Muscles Below the Knee, Mr S Irwin on Acute Arthritis of the Hip in Infants, and Mr Harry Platt on Traumatic Dislocation of the Knee joint In the afternoon Professor V Putti (Bologna) will read a paper on the End Results of Arthroplasty of the Knee joint, Dr Murk Jansen (Leyden) on Hallux Valgus, Rigidus and Malleus, and Mr. E W Hey Groves on the Vital and Mechanical Factors in Bone grafting Some Notes on Bone, Fascia and Tendon grafting will be communicated by Mr A P Mitchell, and the Possibilities of End to end Suture After Extensive Nerve Injuries will be discussed by Miss Forrester Brown A demonstration of Kinematographic records illustrating the Various Types of Gaits in Children will be given by Mr. John Fraser At 7 30 P M. the association dinner will be held On Saturday, June 5th, at 9 30 A M, Sir Harold Stiles will operate and demonstrate cases at the Edinburgh Royal Infirmary.

BY a decision of Convocation on May 11th the degrees of Oxford University were opened to women on the same terms as to men

Sir William Osler has left his library of valuable medical and scientific works to the medical faculty of McGill University, Montreal His house at 13, Norham gardens, Oxford, in which Lady Osler has a life interest, has been bequeathed as the official residence of the Regius professor of medicine in the University

THE strike of workers in the drug and fine chemicals trade may become general A demand is made for an advance of 10s a week in wages for all grades Minimum rates for men are at present stated to be drug grinders, pill and tablet makers, 65s a week; packers, 62s 6d a week, bottle washers, 60s a week

PEOPLE'S LEAGUE OF HEALTH —At the Mansion House meeting on May 11th Mr C J Bond reviewed the loss to the nation occasioned by chronic ill health, and suggested that the individual responsibility of each citizen for his own health should be emphasised It was, he said, wrong to be ill if illness could be avoided The "will to health" was taken up by subsequent speakers

THE LATE MR F J. JOYNES —Francis James Joynes, M R C S, L S A, died recently at his residence, Wanswell, near Berkeley, Gloucestershire, in his seventy eighth year Mr Joynes had retired from active work, but at one time he had an extensive practice at Dursley, Gloucestershire, and was for many years medical officer of health for the Dursley rural district

TRINITY COLLEGE, DUBLIN: POST GRADUATE LECTURES —During the past winter the medical authorities provided four afternoon courses of five or six lectures each, open alike to medical men and all medical students The lectures, dealing with such useful subjects as the pathology of bones, gynæcological pathology, the pathology of nerves, and chemical pathology, were delivered respectively by Mr S Pringle, Dr R J Rowlette, Dr F C Purser and Dr W Fearon This term the Honorary Professor of Dermatology, Dr Wallace Beatty is delivering a course of three lectures on Parasitic Affections of the Skin Dr Gordon Holmes, of London, is to deliver his concluding Montgomery Lecture on the Mechanism of the Conjugate Movements of the Eyes

THE FIGHT AGAINST TUBERCULOSIS AT BRIGHTON —At an enthusiastic meeting under the auspices of the Women's Local Government Association and the Brighton, Hove, and Preston Division of the British Red Cross Society at Hove, on May 7th, the Countess of Chichester presiding, the following resolution was unanimously carried —

> That Parliament be urged to make such provision as will enable local authorities throughout the country to undertake comprehensive measures for the prevention of tuberculosis and for the treatment and care of tuberculous patients and their dependents

Among the speakers were Sir H Kingsley Wood, M P, and Sir Malcolm Morris The former said he believed that Brighton had been the first municipality to provide institutional treatment for tuberculosis He urged the need of proper, up to date, well equipped sanatoriums up and down the country Sir Malcolm Morris spoke of three great factors in the problem—heredity, infection, and environment, the greatest of which was the last Mr H Milner Black, a member of the Brighton Corporation, said 300 or 400 people died from tuberculosis quite needlessly in Brighton and Hove every year, and strongly urged a great campaign throughout the country, not merely to mend the disease, but to end it

NEW CLINICAL LABORATORIES AT SWANSEA —On May 7th Sir George Makins visited the city hospital to open the new clinical laboratories, recently erected through the generosity of Mr Roger Beck Sir George Makins, when performing the ceremony, spoke of the place filled by clinical laboratories in the science and mystery of medicine, the mystery is practised at the bedside, but the science on which it is based is founded on work carried out in the laboratory Without practice there would be danger of the science becoming an abstract study, but without the science practice would become empty empiricism The value of laboratory research had been immense, during the war, in improving the treatment of wounds, in combating the onset of shock, and in disclosing the causation of trench fever During peace, similar valuable results beneficial to the race might be expected from establishment of laboratories such as he was opening He congratulated Swansea on its new institute, which, by assisting the scientific work of the medical profession, would be a material asset to the health of the whole district Professor D Hepburn, speaking for the Welsh National School of Medicine, pointed out that Swansea was fortunate not only in its new institute, but also in its director, Dr. A F S Sladden.

Colonel Sir Edward Thornton, formerly in charge of the South African Military Hospital at Richmond, Surrey, has been appointed chief assistant to the medical officer of health for the Union of South Africa.

Royal Devon and Exeter Hospital and Exeter Dispensary: Proposed Amalgamation.—At the last meeting of the governors of the Royal Devon and Exeter Hospital it was reported that, as a result of a meeting of the representatives of the Hospital and Exeter Dispensary, it was decided to appoint two members of each institution, under the presidency of the mayor, to draw up a scheme for the amalgamation or better working of the two charities.

The late Dr. Symes Saunders.—George James Symes Saunders, M.D., M.R.C.P. Lond., M.R.C.S., L.S.A., D.P.H. Camb., died at his residence at Eastbourne, on April 28th, in his eighty-sixth year. He was educated at Exeter, and received his medical education at King's College Hospital, London. Dr. Symes Saunders was for nearly 50 years resident physician-superintendent at the Devon County Asylum, Exminster, but retired from active work about 15 years ago.

Armenian Red Cross and Refugee Fund: Fifth Annual Report.—The satisfactory balance-sheet of this fund is due less to the actual amount of donations and subscriptions in 1919, than to the fact that working expenses have been kept down to a minimum. It is stated that all work in connexion with this fund is voluntary and practically the only expenses entailed have been those of printing and postage. The needs of Armenia have not diminished, and parcels of clothes, especially socks, stockings, and boots, will be gratefully received by Miss Aganoor, the honorary secretary, Armenian Ladies Guild, 47A, Redcliffe-square, London, S.W. 10. Contributions and all letters relating to the fund should be address to the honorary secretary, Miss Emily J. Robinson, 35A, Elsham-road, London, W. 14.

Municipal Milk.—By a majority of one vote the Manchester City Council has approved the scheme for the municipalisation of milk distribution already outlined in THE LANCET. The proposal will be included in the next Parliamentary Bill. The Health Committee's arguments in support of the proposal were that as supplied at present Manchester milk would all be classed C 3 according to American grading, and would be allowed for use only for cooking and for manufacturing purposes; that impure milk was largely responsible for tuberculosis in children, and that one-third of the deaths of children under 5 years of age could be attributed to bovine infection. If men's beer contained as much dirt as children's milk it would be condemned for consumption. Adulteration was so common that Manchester citizens paid £35,000 yearly for water.

Devon Education Committee and Medical Fees.—At the last meeting of the Devon Education Committee it was reported that the appointment of assistant school medical officer at a salary of £400 per annum had been advertised in lay papers, as the medical papers had refused to insert the advertisement for a whole-time medical officer at a salary of less than £500 a year. Six applications had been received, but five of these withdrew because warning notices had been issued by the British Medical Association, and the remaining candidate was appointed. It was stated that the school medical officer for the Barnstaple district had just resigned, as he found it impossible to live on the salary of £400 a year. Eventually it was decided that the salaries of the school medical officers, which are from £400 to £500 yearly, should be increased annually by £20 until £500 are reached.

The late Dr. P. B. Kelly, D.S.O.—Peter Burrowes Kelly, who died on April 6th, was born in Ireland and received his medical education first in Dublin, where he obtained a medal for chemistry, histology, and medicine, and later at St. Bartholomew's and Charing Cross Hospitals, London. Having obtained the diplomas L.R.C.P. & S. Irel., and L.M. in 1911, he joined the Royal Navy on August 4th, 1914, and served first at Antwerp. He then volunteered for service on H.M. Transport *River Clyde*, the ship which was run ashore at Gallipoli to facilitate the landing of troops. He was wounded in the foot during the disembarkation, but still continued to attend the wounded; for this and other gallant services he was awarded the D.S.O. He served at Gallipoli until the army was withdrawn. His last appointment was at the Royal Naval College at Osborne, where he lived through several severe epidemics before his retirement from the Royal Navy in August, 1919. Immediately after leaving the navy, and without any interval of rest, he commenced civil practice in London, but his health rapidly declined, and he died on April 6th at the residence of his brother, Dr. J. Kelly, Crookstown House, Ballytore, co. Kildare, leaving a wife and one child.

The Royal Society Conversazione. — On Wednesday evening, May 12th, Sir J. J. Thomson, President of the Royal Society, received at a conversazione a large number of guests, for the most part well known in scientific circles. Demonstrations were given in the Committee and Meeting Rooms on the ground floor by Mr. Campbell Swinton (Exposition of Wireless Telephony in connexion with an experimental demonstration by the Marconi Company from Chelmsford); Sir Charles Parsons (Water-Hammer Cone demonstrating the Destructive Effect of Collapsing Vortex Cavities); and Mr. Edwin Edser (the Concentration of Minerals and Coal by Froth Flotation). Among the exhibits of particular medical interest may be mentioned the new instruments and diagrams from the Meteorological Office; a method of demonstrating flagellæ on micro-organisms, devised by Mr. J. E. Barnard and Dr. W. Topley; a demonstration by Professor Nuttall and Dr. D. Keilin of hermaphroditism in the louse; and Professor E. Mellanby's demonstration of the effect of vitamines on puppies.

Chelsea Hospital for Women.—The forty-ninth annual meeting of the Governors was held at the hospital on April 23rd, Sir F. W. R. Fryer in the chair. The report stated that 760 patients had been treated during the past year; the greater number were very critical cases and the rate of mortality was 1½ per cent. only. Increasing costs were giving the council grave concern, and it was feared that without the help of a much larger number of supporters the hospital would be seriously in debt by the end of the current year. The building of a home for the nurses was now an urgent necessity. Pending its completion half the beds in the hospital had to be used to house the nurses and servants, and consequently the list of patients awaiting admission was abnormally high. £7000 was in hand for the Home and £20,000 more was needed. The Convalescent Home at St. Leonards also needed additional support.

The Medical Society of London: Election of Officers and Presentation of Fothergillian Medal.—At the annual general meeting of the Medical Society of London held on May 16th the following officers and members of the Council were elected for the session commencing in October, 1920:—

President: Sir William Hale White.

Vice-Presidents: Dr. F. J. H. Bateman, Sir Hugh Rigby, Dr. Hugh Lett, Sir F. W. Mott.

Secretaries: Dr. W. H. Willcox, Mr. H. W. Carson.

Treasurer: Dr. J. Mitchell Bruce.

Librarian: Dr. Arthur Francis Voelcker.

Honorary Secretary for Foreign Correspondence: Dr. Herbert R. Spencer.

Council: Dr. Donald Armour, Mr. E. C. Bridges, Mr. C. C. Choyce, Dr. F. G. Crookshank, Dr. H. A. Des Vœux, Sir H. J. Gauvain, Dr. C. E. Lakin, Mr. T. P. Legg, Dr. E. E. Lewis, Mr. H. N. Matthews, Mr. C. S. Murray, Mr. C. J. Ogle, Dr. D. Lloyd Roberts, Mr. Percy Sargent, Mr. James Stewart, Dr. P. Montague Smith, Mr. W. W. Stocker, Dr. A. H. Vassie, Dr. G. E. Ward, Dr. Leonard Williams.

The annual oration was delivered by Sir D'Arcy Power, who chose for his subject "The Rev. John Ward and Medicine," which appears in this issue of THE LANCET. The President, Mr. V. Warren Low, on behalf of the society, presented the Fothergillian gold medal for 1917 to Sir Leonard Rogers for his work in connexion with dysentery. In expressing his thanks to the society Sir Leonard Rogers said that his appreciation of the honour was enhanced by the fact that he was a stranger to most of those present and that the medal was handed to him by his old friend and fellow-student, Mr. Low. It was a great encouragement to him to persevere with his work.

The late Dr. J. H. Fullarton.—John Hamilton Fullarton, who died suddenly at his residence in Porchester-gardens on May 6th, was a well-known marine biologist, and in later years he had a large consulting medical practice in the West-End of London. A native of Arran, he was born in 1856, and studied medicine at Glasgow and at Leipzig. At Glasgow University he graduated in science in 1880, obtaining the doctorate in 1891. He passed a brilliant studentship, being Exchequer Bursar in 1876 and winning the John Clark, Jun., Scholarship in 1879. In 1881 he proceeded to the M.A. degree, taking the highest honours in natural science, and in the same year won the G. H. Clark Fellowship in natural science. He was then for some years assistant to the late Professor John Young. In 1906 he obtained the triple qualification of Edinburgh and Glasgow. Dr. Fullarton, who had been an examiner at the University of Glasgow for the M.B., B.Ch. degrees, and a lecturer on biology at Queen Margaret College, was a Fellow of the Royal Society of Edinburgh, and a member of many foreign scientific societies. For some years he was zoological superintendent of the Scottish Fishery Board Marine Laboratory, and his writings on the subject of marine life have been translated into most European languages. A man of decided views, neither science nor medicine filled his whole life, and a few weeks before his death he was engaged in an active campaign at a Scottish by-election.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS

General Medical Council Bill

Sir HENRY CRAIK presented a Bill in the House of Commons on Monday, May 10th, "to amend Section 8 of the Medical Act, 1886" The *Bill*, which was supported by Captain ELLIOT and Lieutenant Colonel RAW, was read a first time The object of the Bill is to provide that all Direct Representatives on the General Medical Council are to retire at the end of a five years' period Vacancies occurring during the five years' period are to be filled only as to the remaining term of that period At present the Direct Representatives on the General Medical Council—that is, those elected by the general body of practitioners—hold office by Statute for five years The result has been that when death has occurred the successor to the dead representative is elected not to finish the term of his predecessor's office but for the full term of five years, with the consequence that elections have been multiplied The present Bill is introduced by Sir HENRY CRAIK, with the goodwill of the Privy Council

HOUSE OF COMMONS

WEDNESDAY, MAY 5TH

War Pensions Bill

Mr MACPHERSON (Minister of Pensions) in moving the second reading of the War Pensions Bill said that the administration of pensions cost as much as £5,000,000 a year The Great War was now over, and the situation had to be reviewed The call for economy was in the air If the transfer of administration proposed in the Bill was not agreed to, it would mean that pensions cases would have to be considered by two different departments Therefore, in the interests of economy and efficiency the Government had come to the conclusion that the administration of post war pensions should be handed over to the Service Departments Nothing in the Bill interfered with the existing powers of the Ministry of Pensions The Bill defined the end of the war as July 31st of this year, and kept alive Section 3 of the War Pensions Act, 1919, which provided for advances of pensions to pensioners for periods not exceeding six months It was further proposed to transfer to the Ministry of Pensions wound pensions to officers The work of the Pensions Committees had become largely stereotyped and standardised, and some of the country committees themselves realised that the continuance of their splendid work was no longer required He was taking power in the Bill to reorganise and regroup the various divisions in the county with a view to securing the best possible administration, while reducing as far as he could the amount of expenditure He proposed wherever he thought it desirable to substitute for the present county committees local committees acting independently over wide areas within the county He also sought powers to appoint a finance officer to take charge of the finance of committees at any time when he thought it necessary in the public interest The Ministry of Pensions would remain with all its powers to deal with the great work which it was called upon to do by various Acts in connexion with the pensions which had arisen out of the Great War All post war pensions would revert, as they would without legislation to the contrary, to the services in which the man had served —Mr HOGGE moved the rejection of the Bill He said that he had hoped that they had destroyed separate pension departments for the separate arms of the forces, but now it was proposed to set them up again —Several honourable Members criticised the decentralising policy of the Bill —The Bill was read a second time

Shortage of European Medical Officers in India

Sir WILLIAM JOYNSON HICKS asked the Secretary for India whether he was aware of the shortage of European doctors in the Indian Medical Service, and whether he was prepared to give an assurance to the Europeans in India that the utmost effort was being made to provide a European doctor within reasonable access of military and civilian officials and their families —Mr MONTAGU replied The shortage of European medical men in the Indian Medical Service has engaged my anxious attention for the last two years, and every effort is being made to overcome it I am alive to the great importance of a sufficient supply of European medical men

Portsmouth Claim for Compensation

Major Sir BERTRAM FALLE asked the Secretary to the Admiralty if he was aware of the claim to compensation made by Robert E Read ex hired skilled labourer, Portsmouth Dockyard, that this man had been ordered to come to London to be reported on by a medical referee, that Read s state of health was such that he could not travel without an attendant, which had been granted by the Admiralty, and must be conveyed in cabs to and from the station and the doctor, if there were no competent and honourable surgeons in Portsmouth who could be asked to report and save this invalid the trouble and pain of a long journey and the State an extravagance, and if he would see to the matter and future and similar cases —Sir J CRAIG replied Arrangements were made for Read s examination by the Government medical referee under the instructions of the Treasury and in accordance with the terms of the Government scheme of compensation In cases in which it is considered sufficient to have the man examined locally this is invariably done, but where the Admiralty and the private doctors disagree it is generally considered advisable to refer such cases for the decision of the referee On the available facts in this case arrangements were made accordingly, but in view of the suggestion that Read is unfit to travel the Treasury is in communication with the medical referee with a view to considering whether arrangements can be made for his examination by a local practitioner

Forthcoming Dental Legislation

Mr GILBERT asked the Minister of Health whether he proposed to bring in a Bill to carry out the recommendations of the Departmental Committee on Dentistry of last year, and if so, could he state when it would be introduced —Dr ADDISON replied A Bill is now in course of preparation, and it is hoped to introduce it before the end of this month

Notification of Births

Sir HENRY HARRIS asked the Minister of Health whether his attention had been called to the difficulty of obtaining convictions for failure to notify births under the Notification of Births Act, 1907, such difficulty being due to the wording Paragraph (3) of Section 1 of that Act, and whether it was proposed to introduce legislation to make effective the obligation to notify births —Dr ADDISON replied I am aware that the wording of the statute has caused difficulties, and the matter will receive consideration

Medical and Funeral Expenses of Service Men

Mr GRATTAN DOYLE asked the Secretary for War and Air if the War Office was empowered to pay the medical and funeral expenses of those officers and men who lost their lives within a few days of their arrival home after having been demobilised, in February, 1919, where it could be shown that the cause of death was the result of illness contracted on the journey through France owing to the authorities having failed to provide suitable accommodation during the journey, the officers and men having been required to travel in cattle trucks and having been held up at the French ports and required to sleep in tents for several nights when the thermometer was at zero, and, if the War Office was not empowered to pay such expenses, if he would obtain the necessary powers to do so —Sir A WILLIAMSON (Financial Secretary to the War Office) replied The powers of the War Office in these matters are not automatically terminated by demobilisation of the person concerned If the honourable Member will furnish me with any specific cases I will have them investigated —Mr DOYLE If the right honourable gentleman will look at the records of the War Office he will find that I have furnished him with some specific cases —Sir A WILLIAMSON I shall be very pleased to make inquiry

Motor-car Rebates for Medical Men

Sir WILLIAM JOYNSON HICKS asked the Minister of Transport whether it was intended, under the new scheme for the taxation of mechanically propelled motor vehicles, to grant any special privileges, exemptions, or rebates in respect of motor cars used by doctors and veterinary surgeons similar to the privileges enjoyed by them under the present system of taxation, and, if not, upon what grounds it was proposed to withdraw the existing privileges —Mr NEAL (Parliamentary Secretary to the Ministry of Transport) replied There is no intention to give special privileges to these classes of motor car users This question was carefully considered by the Departmental Committee on Taxation and Regulation of Road Vehicles, and the reasons for the withdrawal of existing privileges are set out in par 23 of their report The rebates which these users now enjoy were conceded partly in order to bring them into line with commercial motor vehicles, which pay no Inland Revenue duty and are entitled to a rebate of half the duty on motor spirit With the abolition of preferential treatment to commercial users the case for medical practitioners and veterinary surgeons necessarily fails There could be no justification for exempting members of two professions only Every person using a motor car in connexion with his profession or business would be equally entitled to preferential treatment The concession to medical practitioners and veterinary surgeons was made when motor cars were taxed as luxuries This is now no longer the case The proposed tax is in fact, a tax upon road users for road purposes

New Incidence of Income-Tax.

Major STEEL asked the Chancellor of the Exchequer whether his attention had been called to the severity of the proposed scale of graduation of income-tax in the Finance Bill on those whose income was between £600 and £2000 a year; and whether it was a fact that the proposed rate of tax per pound did not increase progressively with income between these two figures.—Mr. CHAMBERLAIN replied: My honourable and gallant friend is mistaken. Tax-payers whose total incomes fall within the limits specified in the question will, as a class, pay substantially less in income-tax under the Budget proposals than they would have had to pay under the law previously in force, and, as is shown by the graphs reproduced in House of Commons Paper No. 71, the effective rate of tax under the new scheme rises by an even progression between the two limits. I may add that the relief given under the Budget proposals to persons having incomes between £600 and £2000 per annum is no less than £3,500,000. There are, of course, individual cases in which the liability will be greater under the new scheme. Those cases arise from two causes—heavier charge thrown upon unmarried persons above £300 per annum and the smoothing of the jumps in the old scale.

Alleged Consumption of Deleterious Compounds.

Mr. CLOUGH asked the Minister of Health if his attention had been called to the alleged growth of the consumption of deleterious compounds, such as methylated spirits, among people affected by the high price and scarcity of ordinary stimulants; whether his department had any information on the subject; and what steps it was taking in the matter.—Dr. ADDISON replied: No evidence has been brought to my notice of the growth of the practice referred to, nor have I any special information on the subject. The cause suggested by the honourable Member is not a matter within my jurisdiction.—Mr. CLOUGH asked the Chancellor of the Exchequer if he had considered the possibility of people consuming deleterious substances owing to the high price and scarcity of ordinary stimulants; and whether he would reconsider the new taxation from the point of view of the public health.—Mr. CHAMBERLAIN replied: I do not share the apprehension entertained by my honourable friend.

THURSDAY, MAY 6TH.

Staff of the Pensions Ministry.

Mr. ROBERT YOUNG asked the Pensions Minister if he would state the number of persons employed by the Ministry and appointed during the year ended March 31st, 1920, at salaries over £350 per year; what was their previous experience of war pensions work or work qualifying them for such appointments; and how many were in receipt of salaries and income from other public funds, not including disability pensions.—Mr. MACPHERSON replied: The number of officers appointed to the Ministry during the year ended March 31st, 1920, and employed at salaries exceeding £350 a year is 51—namely, 13 permanent civil servants, 23 temporary officials with previous experience in other Government departments, 9 ex-Regular army and navy officers, and 6 temporary officials with special qualifications. It is not possible to say how many of the above-mentioned officers had previous experience of war pensions work. Approximately 15 are in receipt of income from other public funds, apart from disability pensions. These numbers exclude 552 medical officers appointed during the same period, of whom 12 are in receipt of income from other public funds.—Mr. SHORT: Can the right honourable gentleman say what public funds?—Mr. MACPHERSON: I cannot say offhand.—Mr. YOUNG: Will preference be given to those who have no pension or income over those who have? —Mr. MACPHERSON: I do not see how that is possible.—Mr. P. BILLING: Surely it is advisable to select from those who have served those who have no pensions or other income? —Mr. MACPHERSON: That certainly ought to be considered, but there are obviously other considerations.

Decisions by Local Medical Referee.

Mr. GRANT asked the Pensions Minister if he was aware that decisions come to by the local medical referee in the cases of disabled soldiers whom he had personally examined could be arbitrarily overruled by the Deputy Commissioner of Medical Services without this official having had opportunity of personal inspection of the cases; and if he could see his way to alter this regulation.—Mr. MACPHERSON replied: I am sending my honourable friend a copy of the revised Circular 804, from which he will observe that the Deputy Commissioner of Medical Services cannot overrule the medical referee on a question of treatment allowances unless and until the man has been re-examined either by the Deputy Commissioner himself or by a medical officer of the region.

Financial Position of the London Hospitals.

Mr. ROBERT YOUNG asked the Minister of Health whether he was aware that some of the London hospitals were in a serious financial position, and that appeals were being made in our elementary schools to the children, and through them to the parents, for assistance to prevent some of them partly closing down or otherwise curtailing their very necessary and beneficent work; and if he would say whether any steps were likely to be taken by legislation or other means to place these institutions on a sound footing to carry on their activities in the interests of the nation.—Dr. ADDISON replied: In view of the urgent representations which have recently been made to me in regard to the financial position of certain of the London hospitals, I am considering what steps can be taken to meet the difficulty, which, I hope, is only temporary, but I am not yet in a position to make a definite statement on this matter, which necessarily involves far-reaching issues.

Health Conditions in Berwick Rural District.

Mr. WILLIAM THORNE asked the Minister of Health if his attention had been called to the report of Dr. McWhir, medical officer to Berwick rural district, about the health conditions of the parish, where the people lived in hovels as a mere shelter from the wind and weather; if he was aware that the medical officer had called attention to the state of the overcrowded dwellings where young men and women were herded together in one sleeping compartment; was he aware that the medical officer also stated that the overcrowding was a close connexion to tuberculous disease; and if he would take action in the matter.—Dr. ADDISON replied: I am aware of the report in question. A report on the housing conditions has also been made by one of my officers. The first requirement is obviously that the district council should press forward with their new housing schemes, and I am taking steps to secure that this is done.

Recovery of Fats from Sewage.

Mr. ALFRED T. DAVIES asked the Minister of Health if he would state how many public authorities now possessed plant for the recovery of fats from sewage; and what steps, if any, were being taken by the Ministry to prevent fats so obtained from being used for the manufacture of foodstuffs —e.g., margarine.—Dr. ADDISON replied: So far as I am aware, there are only four local authorities which possess plants for the recovery of fats from sewage on a large scale. I have no reason to suppose that the fat recovered in these cases is used in the manufacture of foodstuffs. If my honourable friend has any information on the subject I should be glad to be supplied with it.

MONDAY, MAY 10th.

National Insurance Bill.

In reply to questions by Sir J. BUTCHER and Mr. MYERS, Mr. BONAR LAW stated that it was intended to bring the National Insurance Bill into operation on July 5th, 1920, and this would be possible if it passed quickly through its remaining stages. The Government hoped that it would be possible to get the Report and Third Reading stages in the House of Commons this week.

Milk and Dairies Bill.

Dr. ADDISON introduced a Bill "to amend the Milk and Dairies (Consolidation) Act, 1915." The Bill was read a first time.

TUESDAY, MAY 11TH.

Medical Officers at Pensions Ministry.

Mr. ROBERT YOUNG asked the Minister of Pensions whether the medical and other officers employed by the Ministry at salaries over £350 a year, and who, in addition, were in receipt of income from other public funds, were all disabled men; and would he say from which public funds such income was derived, and what was the amount in each case apart from disability pension.—Major TRYON (Parliamentary Secretary to the Ministry of Pensions) replied: The numbers, amount, and source of income from other public funds are as follows:—

No.	Amount of pension, &c.	Source.	No.	Amount of pension, &c.	Source.
1. ...	£120 ...	War Office.	1. ...	£500 ...	War Office.
1. ...	£150 ...	" "	1. ...	£510 ...	Admiralty.
1. ...	£164 ...	Admiralty.	2. ...	£600 ...	"
1. ...	£173 ...	War Office.	1. ...	£600 ...	War Office.
1. ...	£190 ...	Admiralty.	1. ...	£780 ...	" "
2. ...	£365 ...	War Office & Admiralty.	2. ...	£800 ...	" "
			1. ...	£900 ...	India Office.
1. ...	£426* ...	Sudan Govt.	2. ...	£1000 ...	War Office.
1. ...	£440 ...	India Office.	1. ...	£1010 ...	Admiralty.
1. ...	£451 ...	War Office.	1. ...	£1040 ...	War Office.

* This officer receives in addition £120 from the War Office.

The officers referred to are not all disabled, and the amounts given above do not in any case include disability pensions.

Venereal Disease in the Army.

Captain ELLIOT asked the Secretary for War whether he was aware of the continual and alarming rise in the incidence of venereal disease amongst the British troops in France and Germany; whether he would take all possible steps to combat this, and whether in particular the privilege of free leave passes to Great Britain, recently withdrawn from these troops, could now be restored —Mr CHURCHILL replied I am aware that there has been a rise in the incidence of venereal disease amongst the troops in France and Germany since the armistice The subject has received anxious consideration for some months past and I am satisfied that the authorities on the spot are taking all possible steps to combat it As regards the last part of the question, I would refer the honourable and gallant Member to my previous replies The decision was only reached after very careful consideration

The Chief Inspector of Factories, Home Office, S W , gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Blackford, Campbeltown and Gravesend

Births, Marriages, and Deaths.

BIRTHS.

BARNES —On May 3rd at Wiltshire House Wiltshire road, S W , the wife of Howell Wood Barnes, B A , M B , B C Cantab , D P H Cantab , of a daughter

BEAUMONT —On April 28th, at a nursing home, to Norah (nee Hamill), the wife of Dr G E Beaumont—a daughter

BIDWELL —On May 6th, at Woodchurch, near Ashford, Kent the wife of Surgeon Commander Lawrence Bidwell, R N (retired) of a son

CHALLENOR —On May 7th, at The Mount, Rhos-on Sea, N Wales, the wife of Major L T Challenor, R A M C T F , *of a daughter*

CROSBIE —On May 3rd, 1920, the wife *of* Douglas F Crosbie, M D , M C , Clarendon terrace Londonderry, *of a* daughter

MENZIES —*On May 10th, at* Egerton gardens, the wife of Dr F N Kay Menzies of a son

SEYMOUR-PRICE —On May 9th, at Sloane gardens, S W , the wife of Dr P Seymour Price of a son

TRETHOWAN —On May 9th at St Thomas s street S E , the wife of W H Trethowan, F R C S , of a son (John Durham)

THOMPSON —On May 4th at Priory mansions, Drayton gardens, the wife of Major W I Thompson, D S O , R A M C , of a daughter

MARRIAGES.

BISHOP—SCARBOROUGH —At Sheffield, on May 12th, Major Raymond S Bishop, M C late Lincolnshire Regt , to Hilda Mary Scarborough, M D

RIDDELL—STEVENS —On May 5th, at the British Consulate General, Antwerp and afterwards at the Church of St Boniface, Antwerp, Daniel Falconer Riddell M C , M B late Captain, R A M C , to Honor Paynter, eldest daughter of Mr and Mrs H W Stevens, Antwerp

SCOTT—KELLS —On April 29th, at St James s Church Piccadilly, W , Evelyn Denis Scott M B , M R C P B S , to Muriel Evelyn Kells elder daughter of Mr and Mrs John Kells, of Gerrard s Cross, Bucks

DEATHS.

INGLIS —On May 10th, at Eversfield place, St Leonards-on Sea, John Inglis, M A , M D , aged 59 years

N.B —A fee of 7s 6d is charged for the insertion of Notices of Births, Marriages, and Deaths

Notes, Short Comments, and Answers to Correspondents.

MEDICAL OFFICERS' EMOLUMENTS ON THE RAND.

WRITING on behalf of the East Rand Branch of the South African Medical Association, the secretary of the Association has intimated to the Kleinfontein Group Medical Society that the Association disapproves of the present rates paid by the society to its medical officers In view of the increased cost of living fair rates are urged The letter states · "We must therefore ask you to raise the fees paid to at least 4*s.* per head per month for whole time appointment, or—should you feel that your medical officer can undertake private practice without detriment to your members—3*s* 6*d* per head per month This will bring your society more into line with other societies along the Reef." The letter concludes imperatively "We feel that one month will give you ample time to make up your minds on the question, and we have therefore decided that Dr. Drever must cease work at the end of April unless our rates are agreed to " In reply, the secretary of the Kleinfontein Group Medical Society states that his committee is of opinion that the demand is unreasonable "The committee is quite prepared to pay a reasonable increase on the basis of the increased pay that the men themselves have received. They have obtained 40 per cent on their 1914 rates, and some have received only 20 per cent. The present appointment was advertised in 1913, and there were 30 applications from all parts of the Union and from Rhodesia, and there was one from England. The salary was £1000 per annum in January, 1914. The society granted a motor car allowance of £100 per annum In May, 1916, on threat of resignation, the salary was raised to £1500, and the demand now made was equivalent to £2500 per annum, plus private practice, estimated to be worth an additional £500 per annum "

INTRAVENOUS EUSOL IN MALARIA

Lieutenant Colonel P S Vickerman describes in the *Journal of the R A M C* for January ten cases of obstinate subtertian malaria treated successfully by intravenous injections of eusol after quinine had ceased to show effect Forty c cm was the usual dose of eusol containing 5 per cent. of hypochlorous acid, the solution must be freshly prepared Crescents disappeared first, then the other forms Blood counts, numerical and differential, improved, and a patient with malarial cachexia said he was a new man If other observers will give this method trial, and find results as hopeful, a great advance in the treatment of malaria will be to the credit of Lieutenant Colonel Vickerman, whose observations appear to have been made in Egypt

FOOD SHORTAGE IN SKYE

THE condition of the people of Skye and the Outer Islands owing to the prevailing food shortage was discussed at a meeting of the Inverness shire education authority in Inverness on April 29th Mr Nicol Martin, of Glendale read a letter which he had received from a retired teacher on the property of the Board of Agriculture in Skye The writer stated that last December and January, while influenza was raging, there was not an ounce of food but a few hard biscuits and some potatoes There was no milk except that of two cows, and this was distributed among the sufferers Six deaths occurred in that small district, including three school children Had their systems not been reduced by want of nourishment they might have survived, but they lacked any power of resistance During the same period the year before the position was as bad Out of 46 children in school one only had a piece of bread, and in only one house was there a grain of meal The situation was desperate and he (the writer) had sent to Portree for ten dozen loaves This relieved the position, as he was able to distribute 2 lb of bread to each person in the district The teacher who got supplies by post, often had to feed the younger pupils Some of those children left home at 9 A M and returned at 3 30 without having had any food, and with potatoes only awaiting them at home Several families remained away from school for want of food Rev Mr McLeod, North Uist, corroborated what Mr Martin had said, and added that the hardship was felt all over the Western Islands There were many children in Benbecula who had to be kept at home for fear they would faint in the schools The clerk stated that, in reply to their representations on the subject, an acknowledgment had been received from the Scottish Office, and a letter from the Ministry of Shipping stated that the matter was receiving very close attention, and that they would do all in their power to improve matters in connexion with transport facilities in Skye

OFFICIAL FOOD ANALYSIS IN VIENNA STOPPED.

WE learn from the *Economic Review* (May 5th) that the food analysis office in Vienna has been closed. The statement is as follows:—

> A notice has been posted up at the entrance to the Vienna Institute for Food Analysis announcing that the institute is closed till further notice. As to the reason for the sudden closing of an important public office no explanation from official quarters is yet forthcoming. The director of the institute, Dr. Schattenfroh, stated that he could make no communication, as he considered it a private matter. The public is therefore left to form its own conclusions.
>
> It is said that the costs of working have risen so enormously that the sum allocated in the Budget in quite insufficient. This is specially the case as regards the necessary reagents and chemicals. The costs of food analysis, however, are said to be charged always to the manufacturer or the vendor and covered by an increase in the price. Moreover, there are now very few foodstuffs whose exact analysis is necessary, since the majority of the population in the present scarcity will eat articles which in former times would not only have been rejected by the consumer, but prohibited because of their contents. The trade in food substitutes is so general that it is considered superfluous to investigate whether a certain article contains the alleged ingredients, so long as it is not actually injurious to health. The sphere of activity of the Food Analysing Institute is, therefore, very limited. The Office of Public Hygiene will no doubt reopen the institute as soon as possible. In the meantime the laboratory is available for the Vienna Chemists' Institute. (*Neue Freie Pr.*, Apr.8.m.)

The position must be serious when it is admitted that the trade in food substitutes is so general that it is considered superfluous to investigate whether a certain article contains the alleged ingredients so long as it is not actually injurious to health. It is not clear whether control has ceased also in regard to injurious ingredients. The public health may well suffer under this order.

THE PARAFFIN TREATMENT OF BURNS.

THE paraffin treatment of burns is a great advance, but its technique is being improved, and, in the *Journal of the R.A.M.C.* for February, Lieutenant-Colonel A. J. Hull describes the precise method he, after much experience, has come to consider the best. The résumé which follows is very much in his own words. The burn is washed or painted with 1 per 1000 aqueous flavine solution, followed by the application of No. 7 paraffin. "No. 7" paraffin is thus prepared. Melt 678 g. of paraffinum durum, add 250 g. of vaseline and 50 c.cm. of olive oil, with 2½ g. of β-naphthol (resublimed). Let the temperature of the mixture sink to about 55° C., then add 20 c.cm. of eucalyptus oil; stir and allow to solidify. The burn, which has had an antiseptic solution painted over it as we have said, is dried with gauze or an electric drier. A layer of paraffin is applied at a temperature of 55° or 60° C. A thin layer of wool is placed over the first layer of paraffin, and a second layer of paraffin at the same temperature painted over the wool. A dressing of wool and bandage covers the paraffin dressing which is changed every 24 hours. The paraffin should not be too hot or the layer will be too thin and will not peel off in a sheet. This dressing protects the epithelium and holds the tissues at rest, but if granulations become sluggish a scarlet red paraffin should be substituted ("No. 10" paraffin, which takes more trouble to prepare; see the paper). This treatment obviates pain, sepsis, and other complications, so is generally applicable. No other preparation has given so good results.

HOME HYGIENE.

WITHIN the limits allotted to the little manuals issued by the St. John Ambulance Association for the instruction of their students in health matters Dr. John C. Thresh[1] has contrived to write a valuable and comprehensive book on domestic and personal hygiene. As medical officer of health, and now consulting medical officer for a home county, he has had opportunities of closely studying those conditions, the presence or absence of which determines the health, and therefore the efficiency, of the community. The 13 chapters into which the book is divided embody the substance of six lectures dealing with disease in general, its cause, and prevention, the house and its construction, the hygiene of economy, and the rôle of air, water, food, and clothing. The author points out that it should be the aim of every citizen not only to maintain his health up to normal standard, but to raise the health standard of the race. What is required to strengthen the awakening health conscience of the nation is a right understanding of health and its meaning to the community and a knowledge of what is being done by the State and the medical profession in this direction. Dr. Thresh briefly but clearly brings out these points in his early chapters by reference to health statistics, the work of the medical officer of health, the uses of tuberculosis dispensaries, sanatoriums, school inspection, maternity welfare, and so forth. The chapters on lighting, heating, and ventilation contain useful illustrative diagrams, and in the section on food the reader is properly introduced to the important subject of vitamines. An appendix calls attention to the serious menace to health of venereal disease and to the special centres for treatment now opened up in nearly every county. The book is a thoroughly practical one and should be studied and assimilated by every intelligent adult in the country, and especially by adolescents whose tendencies have not yet hardened into habits.

ROYAL WEST SUSSEX HOSPITAL.

OWING to many generous subscriptions, donations, and valuable gifts made during the year, coupled with the fact that many of the patients were paid for by the War Pensions Committee or the County Council, the annual report of the Royal West Sussex Hospital at Chichester shows a balance of £35 6*s*. 2*d*. Since donations and gifts could not be depended on, an appeal was made at the annual meeting on April 29th for a steady income from subscriptions. Expenditure had risen from £5000 before the war to £9140. Under the direction of Lady Garland, at that time Mayoress of Chichester, the Alexandra Day Committee had organised a fête in Priory Park, which resulted in a sum of £881 19*s*. for the hospital. A balcony had been named the "Lady Garland Balcony" as a slight acknowledgment of this lady's efforts. During the year £2000 had been received from the British Red Cross Society, and £500 from the Midhurst Farmers' Red Cross Sale Committee. The governors decided that these sums should be utilised in making structural alterations and improvements, and also sanctioned the allocation of a legacy to necessary improvements to the laundry. The innovation of a pound day at this hospital during the year had proved a great success, and the X ray department had been thoroughly reorganised. Dr. E. H. Buckell, who had been succeeded by Dr. H. E. Rutherford as honorary physician, was appointed honorary consulting physician. The hospital dealt with 858 in-patients during the 12 months.

THE centenary of Florence Nightingale's birth was celebrated this week. She was born at the Villa La Columbaia, Florence, on May 12th, 1820.

Address

NEO-NATAL MORTALITY.

Being the Frederick A. Packard Lecture of the Philadelphia Pediatric Society, delivered on Feb. 10th, 1920,

BY SIR ARTHUR NEWSHOLME, K.C.B., M.D., F.R.C.P. LOND.,
LATE PRINCIPAL MEDICAL OFFICER OF THE LOCAL GOVERNMENT BOARD.

GENTLEMEN,—While I highly appreciate the honour of giving this Packard Lecture to the Philadelphia Pediatric Society, I realise the impossibility of making any medical contribution to your specialty and the necessity of limiting myself to the public health aspects of my subject, in which I have for many years been concerned. I also appreciate the difficulty arising from the fact that my remarks relate to obstetrics more than to pediatrics. Although I do not venture to define the line of demarcation between these special branches of medicine, much of the success of the work of pediatrists depends on the normality of the expectant mother and of the unborn infant, not only in regard to mental development, but also more generally; and the conditions likely to aid in securing normal birth and adequate skilled care in the first weeks after birth are of vital interest to you.

Among the outstanding events in the medico-sociological history of the last 50 years a foremost position must be given to the steady decline of the birth-rate, which has occurred in most civilised countries, and to the increased attention devoted to the welfare of infants and their mothers.

BIRTH-RATE IN RELATION TO INFANT MORTALITY.

It would carry us too far afield to discuss the lowered birth-rate and its undoubted relation to the decrease in infant mortality, owing, in part at least, to the fact that small families occur in social circumstances which otherwise favour infantile survival. Let me, however, state categorically the following points, which need to be borne in mind. In districts and countries in which no reduction of the birth-rate has occurred infant mortality has declined. In countries in which both rates have declined the birth-rate (as in England) was declining steadily for over 20 years before any decline of infant mortality began. Many districts with a low birth-rate have a high infant mortality-rate; and although a large family, especially if not adequately spaced, may mean impoverishment and poverty of parents, with neglect of children in essential respects, there is no reason to think that a correspondingly large family under improved social conditions would be otherwise than favourable to a healthy and ideal family life.

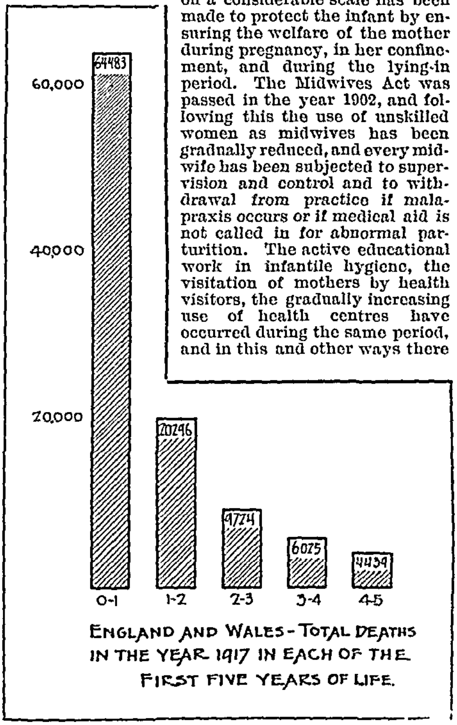
The lowered birth-rate has undoubtedly been one of the factors leading to recent activities to secure the preservation of child-life. The single statement that in England and Wales 9000 fewer births took place weekly in 1914, before the effect of the war began to be felt, than would have occurred if its population had experienced a birth-rate equal to that of the year 1876, and that in consequence a decrease of about half a million fewer births resulted, serves to remind us that although in England our growth of population by excess of births over deaths still amounts to 1 per cent. per annum we are approaching, unless the course of events is changed, a period when natural growth of population will cease, and England—and I may also add America—will be dependent on immigration for further increase of population.

In passing from this aspect of the subject it is not inappropriate—the child being the wealth of the future—to recommend the avoidance of "the sad heresy of celibacy" (*Punch*) and the contracting of early marriages, especially by those who now disproportionately avoid them, as necessary not only in restoring and maintaining the success of family life, but also in securing the same standard of sexual morality for both sexes and in avoiding the ravages of gonorrhœa and syphilis, two of the greatest enemies of child-life and of maternal health.

Dr. Emmett Holt,[1] in an interesting historical sketch of infant mortality, has drawn attention to some of the more important motives which have led to the increased attention which has been given to this subject in the last 40 years. In France, which led the way in respect of the day nursery, of societies for encouraging maternal nursing, and of *gouttes de lait*, the failure of the population to increase undoubtedly had great influence in securing action. In England attempts at controlling infant mortality began on definitely public health lines. But it was not until 1902 in England that a definite and continuous reduction in infant mortality began; and in the production of this result a large share of credit must be given to the "concentration on the mother and the child" which has been a striking feature of the last 20 years.

It is chiefly during the last ten years that action has extended towards the point at which logically it ought to have begun, and organised effort on a considerable scale has been made to protect the infant by ensuring the welfare of the mother during pregnancy, in her confinement, and during the lying-in period. The Midwives Act was passed in the year 1902, and following this the use of unskilled women as midwives has been gradually reduced, and every midwife has been subjected to supervision and control and to withdrawal from practice if malapraxis occurs or if medical aid is not called in for abnormal parturition. The active educational work in infantile hygiene, the visitation of mothers by health visitors, the gradually increasing use of health centres have occurred during the same period, and in this and other ways there has been increasing effort to restore to its former integrity family life, which had been seriously encroached upon by the conditions of town and industrial life. It is not one of the least of the valuable by-products of the calamitous World War that it has done much to restore the status and ideal of motherhood, and to make us realise that on this depends the future well-being and happiness of mankind.

FIG. 1.



ENGLAND AND WALES–TOTAL DEATHS IN THE YEAR 1917 IN EACH OF THE FIRST FIVE YEARS OF LIFE.

In considering infant mortality we first of all think of it as part of general mortality at all ages. The primary objects of preventive medicine are to transfer as many deaths as possible from the earlier to the later periods of life, to prevent the larger mass of non-fatal illness which, from the point of view of the community, is even more serious than early death, and to raise the general standard of health of the population.

We scarcely realise the difference between the number of deaths in each of the first five years of life. This is shown graphically in Fig. 1.

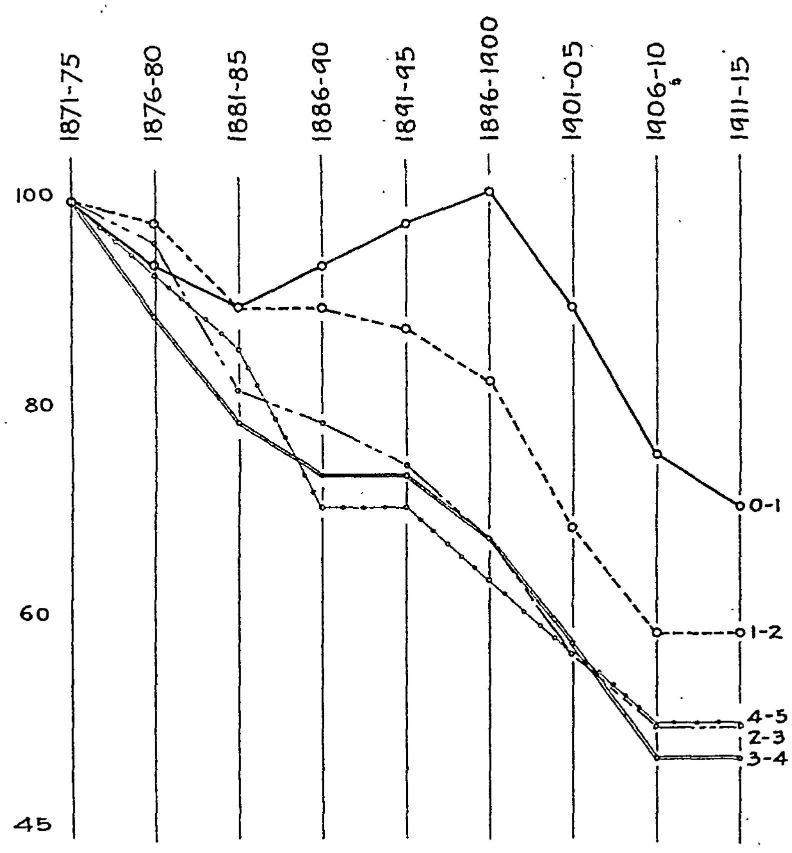
---

[1] Archives of Pediatrics, vol. xxx., No. 12, December, 1913.

Fig. 2 shows how much more slowly infant mortality in infancy has been brought under control than mortality in the next four years of life.

In view of the commonly entertained error that infant mortality may, on the balance, be selective in character, securing survival of the more robust, it is noteworthy that the parts of England which have the highest infant mortality continue at higher ages to experience a higher death-rate than more favoured districts. Any possible elimination of the weakest by natural selection which may have occurred is accompanied to a preponderant extent by the manufacture of weaklings and by an excessive death-rate at older ages, due to continuance throughout the whole of life of the evil conditions which caused the excessive infant mortality.

FIG. 2.



ENGLAND AND WALES—RELATIVE DEATH-RATES FOR EACH OF THE FIRST FIVE YEARS OF LIFE IN QUINQUENNIAL PERIODS FROM 1871-75 TO 1911-15, THE DEATH-RATE AT EACH AGE-PERIOD IN 1871-75 BEING STATED AS 100.

From the economic standpoint attack on infant mortality offers abundant scope for action. Here is a period representing about one-eightieth part of the whole life; but in this period 1 out of 9 or 10 total deaths occurs; furthermore, the state of health in infancy in large measure determines the health standard of the whole of life.

From the same standpoint the mortality under one month, first described by Ballantyne as neo-natal mortality, also is especially important. At least one-tenth of the total deaths at all ages occur in infancy; one-half of these infantile deaths occur within the first three months, one-third within the first month, and one-fifth within the first week after live birth.

If, therefore, it were practicable to halve these early or neo-natal deaths a greater saving of life could be obtained than by halving the death-rate at any other period of life of equal length. There is ample work for further preventive measures against infant mortality in the last 11 months of the first year; but the most fertile and least tilled soil is that of the neo-natal period.

In view of the statement commonly made that infant mortality during the first month is chiefly due to developmental conditions, and is practically beyond control, let us examine mortality in this period more closely. In Fig. 3 the share which developmental and wasting diseases have in causing total infant mortality is shown. It will be noted later that it bears a very varying part in different counties of England. In this diagram the above group of diseases includes deaths from premature birth, congenital defects, injury at birth, want of breast milk, atrophy, debility, and marasmus. I have purposely grouped all these together because of the unsatisfactory certification of causes of death of infants dying in the earlier weeks of life. Throughout the whole of infancy medical certification of deaths is much less satisfactory than for deaths at any subsequent age, and it is of but little use to advise physicians to be more accurate in their certificates until we have more exact pathological knowledge of the causes of early infant mortality. Some valuable research work has been done in this field, but it needs to be greatly extended, and such work would doubtless add greatly to our armamentarium against early infant mortality.

In an official report I have analysed the above group of causes of death further, and it appears that nearly 90 per cent. of the deaths from premature birth and congenital defects, and about 40 per cent. of the deaths from atrophy, debility, and marasmus occur in the first month after birth. It appears, further, that there has been much transfer of certification between these various headings, and that it is probably not justifiable to infer, as has often been done, that the mortality from premature birth has increased in recent years.

NEO-NATAL MORTALITY NOT IRREDUCIBLE.

We are on safer ground when we base our conclusions on total deaths in the first week and in the first month after live birth; and in view of the accurate registration of births and deaths in England I may be excused for taking illustrations from past official English reports. The facts set out below give an effective quietus to statements that neo-natal mortality is practically irreducible.

The following figures from my official report on Infant and Child Mortality (Cd. 5263), which gives death-rates for the year 1908, show the relative proportion of mortality in different parts of infancy, and the neo-natal mortality in different areas.

Infant Death-rate per 1000 Births.

—	Under one week.	Under one month.	Total under one year.
England and Wales	24·3	40·3	120·4
County of Durham	33·8	52·1	151·0
„ Glamorgan ...	24·8	46·1	154·3
„ Hereford	18·2	31·2	75·8
„ Oxford	20·9	30·6	73·0

Infant Death rate per 1000 Births among—

	Infants in first week after birth		Infants in first month after birth
Workington	41 4	Workington	61 0
Dewsbury	41 4	Blyth	58 0
Batley	37 5	Batley	57 7
Barnsley	31 2	Dewsbury	56 7
Bradford	30 7	Aberdare	49 4
St Helens	30 3	Walsall	49 3
Doncaster	19 7	Guildford	29 4
Edmonton	19 1	Holborn	28 0
Crewe	19 0	Penge	27 2
Heywood	16 9	Watford	25 9

It is evident that neo natal mortality varies greatly in different communities It varies also greatly in different sections of the same district, whether it be urban or rural There is no reason to assume that there are any such general variations in the vitality or physical efficiency of mothers as will explain these differences, and we must, I think, conclude that a large share of the loss of precious lives shown above is caused by removable influences, post natal, as well as natal and pre natal

Dr. T. H C. Stevenson in the English Registrar General's Annual Report for 1913 has given data from which it can be inferred that in England and Wales nearly 25 per cent of the total births occurred under circumstances involving a sacrifice during the first month after birth of nearly 50 per 1000 of the infants born; while for over 2 per cent of the births the corresponding sacrifice was only 20 per 1000 of those born. Nor could social position be brought forward in explanation of this extraordinary discrepancy, for in the most unfavourable group were infants of waiters, navvies, textile workers, dress makers, coal miners, and many others, while in the favourable group were infants of copper miners, motor mechanics, hosiers, boot dealers, glove makers, and many others

We must, therefore, accept the highly satisfactory conclusion that *this early infant mortality is in large measure preventable*

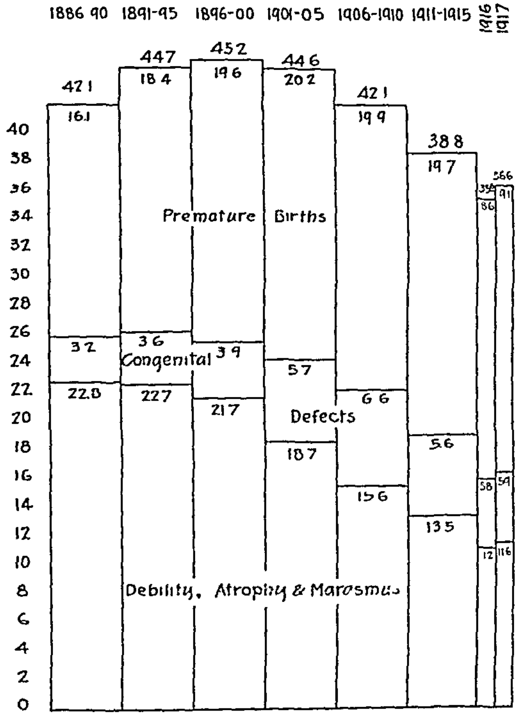
DO INFANTS "START FAIR" AT BIRTH?

Before considering means for preventing preventable mortality, we may glance at the fellow fallacy to the one exposed above—viz, that infants start fair at birth, or in other words are born in a fairly equal state of health It is worth while to pursue this inquiry, inasmuch as incidentally it reveals some of the more important lines along which the prevention of neo natal mortality must proceed Converging lines of evidence demonstrate the error of the above statement —

(*a*) The enormous differences in mortality in the first week and in the first month after birth must in large part be due to differences existing at the time of birth If further evidence is required, it is furnished by

(*b*) The varying prevalence of syphilis in different circles Thus Dr. Stevenson has shown that the death rate from syphilis in illegitimate infants is eight times as great as that of legitimate infants; and although similar statistics cannot be given for other classes, we know that syphilis is a large and varying cause of illness of mothers, of stillbirths, and of serious disease and mortality in infants born alive

FIG 3.



ENGLAND AND WALES—DEATHS OF INFANTS UNDER ONE YEAR PER 1000 BIRTHS FROM "DEVELOPMENTAL" AND "WASTING" DISEASES FROM 1886 TO 1917

(*c*) The statement that infants at birth "start fair" receives no support from the statistics of stillbirths. For several years in England stillbirths from the twenty eighth week of pregnancy have been required to be notified to the medical officer of health It is likely that the law has been complied with to a varying extent in different localities, but this can scarcely explain the fact that while, on an average, stillbirths number 3 to every 100 live births, in some localities the proportion is as high as 7 or 8 Given such variations, it is inconceivable that they can fail to be associated *with corresponding variations in the health of the* mothers and of infants born alive under corresponding conditions.

(*d*) The experience *of illegitimate infants forms* a striking reflection on the opinion that infants start fair at birth. Although the number of illegitimates is small in proportion to the number of births in matrimony, they form a field of social and public health work which, if cultivated, would materially reduce infant mortality This is urgently called for by every humanitarian instinct In the past it has been thought necessary—as likewise in the treatment of venereal diseases—to associate such assistance as is doled out with conditions marking the donors' sense of the moral obliquity of the recipient.

which has rendered help in large measure futile. Among the most sinister of methods of helping unmarried mothers is the one which insists on parting the mother and infant as soon as possible; and yet this has been the method adopted by many agencies in this field, regardless of the elementary fact that the most hopeful action, not only in saving the life and maintaining the health of the infant, but also in lifting the mother out of the morass into which she has fallen, consists in rousing and maintaining maternal love.

(*e*) A most important factor in the causation of neo-natal mortality, and the saddest evidence of all that infants do not start fair, consists in the enormous variations in the incidence of sickness and deaths of mothers during pregnancy and in child-bearing.

This can be seen for England and Wales in the map given opposite p. 12 of my Report (1914–15) on Maternal Mortality in Connexion with Child-bearing (Cd. 8065).

We can divide this mortality into two groups—due to sepsis and due to other conditions—of which renal disease is the most important.

It is doubtful whether any decrease in the death-toll from causes other than puerperal sepsis has occurred. On the other hand, puerperal sepsis has shown a marked decline, and it is impossible to dissociate this from the passing of the Midwives Act, 1902, and the administrative control which has been secured over midwives, who now attend about three-fourths of the total births in England and Wales, subject to the rigid condition that medical assistance must be obtained in the event of abnormality in the case.

It is more than unsatisfactory, however, to find that, notwithstanding the teaching of Semmelweis and of Oliver Wendell Holmes, and the discoveries of Pasteur and their application in Listerism, it is still true in England that for every 700 infants born alive one mother loses her life from puerperal sepsis; that a much larger proportion are invalided from the same cause; and to recall that this mortality and disability occur chiefly as the result of neglect or ignorance in the practice of individual obstetricians, medical or midwives, and from the failure of the community and its representative public health authorities to provide adequate skilled assistance in the one chief event in the national life with which is wrapped up the future and the future welfare of mankind. It is difficult to obtain comparable American statistics, owing to defects in birth registration; but the position in the United States is not less unsatisfactory.

The record for diseases commonly regarded as non-septic is even more unsatisfactory. No improvement can be seen during the present century. Of the total mortality due to pregnancy and parturition the proportion due to different causes is approximately as follows:—

Puerperal sepsis	31·7	per cent.
Puerperal albuminuria and convulsions...	21·6	,,
Puerperal hæmorrhage and other accidents of childbirth	25·5	,,
Other puerperal conditions	10·4	,,
Accidents of pregnancy	10·8	,,

The bare statement of facts gives important indications of the degree to which preventive measures might be adopted.

SURVEY OF POSSIBILITIES OF IMPROVEMENT.

The preceding very imperfect review of some of the causes of neo-natal and maternal casualties should naturally be followed by a survey of possibilities of improvement. As a general hygienist I cannot discuss the special obstetrical, gynæcological, and pediatric problems involved, but as these problems are coming more and more within the scope of public health administration I may be allowed to sketch what is being done by public health authorities, and what it appears to be desirable to do generally, in order to enable every mother and infant to have the best care which modern medicine renders available.

(1) *Need for Continuity of Supervision.*

I would plead that this subject of care of the mother and the newborn infant should not be placed in a compartment separate from general medical care on the one hand or from general public health administration on the other. At every point the general hospital or private physician will be needed; and departments of public health work must be called in aid.

Still less should there be a lack of continuity of observation and care during pregnancy, post-partum, and in infancy, even though different physicians are employed. For medical students one of the greatest desiderata is that they should become practically and continuously acquainted with patients while these are under supervision in pregnancy, during and after parturition, and in the subsequent months when there are two patients instead of one. This evidently can only be secured by having at hospitals in all medical teaching centres, pre-natal clinics, pre-maternity beds for complications of pregnancy, lying-in beds in the hospital, as well as a home clientele, and beds for complications in or after parturition; a post-natal clinic, and a complete system of home visitation of mothers and infants; a clinic for the period between infancy and school life; and a school clinic. And, although perhaps in less elaboration, the above enumeration represents the essential needs of every community.

(2) *Ante- and Post-natal Clinics.*

The best plan for securing a pre-natal clinic is to begin with a post-natal clinic for mothers and infants. Dr. F. S. Kellogg has pointed out that all post-natal care is pre-natal care for the next infant; and that no inconsiderable share of illness of mothers, and of consequent failure in their efforts at child-bearing, is due to neglect of supervision and care after the ten days of the parturient period.

The amount of life- and health-saving attainable by a pre-natal clinic is less than can be secured by improved care in the lying-in period; but probably one-half of the still-births could be prevented, and much of the existing discrepancy in infantile death-rate during the first week after birth could be removed by increased care during pregnancy. Pre-natal clinics have already been largely developed both on their educational and clinical sides; and on the clinical side, in addition to the treatment of minor ailments, the health prospects of both mother and infant can be improved by measurement of the pelvis, ascertainment during advanced pregnancy of the presentation, periodical testing of the urine, and determining whether the mother has become infected by syphilis or gonorrhœa, and by appropriate action in each case.

Although no further mention is made here of the diagnosis and treatment of syphilis during pregnancy, I regard this as one of the greatest gains obtainable from the ante-partum observation of mothers.

(3) *Skilled Care During Parturition.*

Skilled care during parturition is even more important than ante-partum care; and it is at this period that the greatest saving of both maternal and infantile life can be secured. It is, I believe, agreed among obstetricians that more infants of viable age die during labour from injury or accidental complications than die from disease during pregnancy. Dr. Eardley Holland states that of 100 dead-born viable fœtuses he found that generally 40 were macerated and 60 were fresh. In a preliminary statement as to an investigation made for the Local Government Board of England he reports that post-mortem examination in about half of the fresh dead-born fœtuses showed severe cerebral injury in the form of cerebral hæmorrhage and tearing of the septa of the dura mater, owing to excessive stress on the cranium in labour from such causes as delivery by forceps or versions carried out for abnormal presentations.

It has been suggested with doubtful accuracy that the administration of chloroform in parturition has increased puerperal mortality, because of the increasing frequency of operative interference. Protracted delay and consequent moulding of the soft cranial bones in very narrow or otherwise obstructive pelvic passages may, however, do harm as well as hasty delivery by forceps with an undilated cervix.

It should be noted that difficult delivery is an important factor in the production of mental impairment of the child; and in every instance of difficult labour an accurate and early diagnosis of conditions is required in order that the best treatment may be given.

The details of care required in parturition can only be briefly indicated. They include the provision of a trained obstetrician (physician or midwife) for every case, with consultative assistance when required; and adequate nursing help in every case. The strict enforcement of surgical cleanliness in technique should not require to be emphasised; and it is a subject for grave thought that there is still lack in this respect. This lack is not likely to be completely met until the next condition is fulfilled; a condition so important that I give it a separate paragraph.

(4) *Provision of Maternity Homes and Hospitals.*

A greatly increased provision is needed, especially in smaller towns and in country districts, of maternity homes and hospitals where mothers may be confined. These are required, first of all, because the mother must have adequate rest during this trying period of her life. They are required also because many of the homes of the poor are not satisfactory to have confinements in. It is to our shame that this is so, but it is so all the same. Take a simple fact like this: At the last census, in large towns in England—and I do not think the house famine in large towns is less severe here—one out of every seven families lived in one or two rooms, one out of four, or more accurately 27 per cent., lived in dwellings containing one, two, or three rooms. In these small tenement dwellings every function of life has to be carried on; children are born in them and they die in them; and it is evident that, so far as a large proportion of those homes are concerned, unnecessary risks are incurred in connexion with the lying-in period. You may say that this is a strong reason for housing reform. This is so, but the provision of adequate housing will take time. Furthermore, even satisfactory houses without proper help during the lying-in period do not suffice, and, both because of functional and structural defects of the home, it is extremely important for a large proportion of lying-in women that they should have the rest and superior attendance which can be given in a lying-in home, but which are unattainable in their own homes. I know of no social work which is so certain to give immediate results in the saving of maternal and child life, in reducing invalidism of mothers, and in enhancing the national welfare as the immediate provision in every area throughout the country of maternity homes and hospitals for a considerable proportion of normal confinements and for the majority of complicated cases.

(5) *A Raised Standard of Midwifery Practice throughout the Country.*

The average standard of midwifery practice at present is admittedly unsatisfactory. In a recent discussion on "The Teaching of Obstetrics and Gynæcology" at the Royal Society of Medicine, London, Dr. H. R. Andrews said that "the whole system of midwifery training had turned out a certain number of fully qualified medical practitioners who were nothing less than a danger to the State"; and he particularly illustrated "cases in which skilled help was not called in until brute force had done its worst." Although such extreme cases are exceptional, it appears to be generally agreed among experts in England that notwithstanding the overcrowded state of the medical student's curriculum at least three, and some urge six, months should be devoted by each student to maternity and gynæcological work, including work in pre-natal and post-natal clinics. When this is done, and when in every teaching hospital there is an adequate service, including pre-natal clinics, pre-maternity beds, beds for normal and complicated midwifery, beds for post-partum complications, post-natal clinics and infant consultations, the physicians of the future can be adeqately trained to meet the growing public demands for supervision and care in normal and abnormal pregnancy and in parturition, and for post-partum care of the mother and post-natal care of the infant.

Services like the above are needed not only in centres of medical teaching, but in every town, and even in cottage hospitals beds for the same purposes should be supplied. The problem will need to be faced in America whether adequate provision shall be made for medical attendance at every confinement, and practice by unqualified midwives forbidden; or whether, while prohibiting unqualified practice, trained midwives shall be allowed to practise midwifery, as in England, under strict supervision and control. Evidently there can be no prohibition of unqualified midwifery practice unless an alternative provision is available.

(6) *The Need for Further Research in Ante-natal Pathology.*

The existing system of notification or registration of stillbirths opens up a large field of investigation and practical help which has been greatly neglected in the past. Dr. Whitridge Williams found that the death of the fœtus after the seventh month of pregnancy was due to syphilis in 26·4 per cent.[2] of the total cases of stillbirth, and other authorities place this proportion at about 20 per cent. Evidently systematic inquiry followed by action in these cases would result in a great reduction of syphilis, as well as in an increase of live births.

Through the same channel important gaps in our knowledge of the causes of stillbirths and of earlier abortions might be filled. I am aware that a number of important observations in these directions are being made, but there is need for more extensive work in investigation; and there is no field in which such investigation holds out a more promising prospect of success in the saving of life.

Our knowledge on many points in ante-natal pathology is still very defective, notwithstanding the pioneer work by Ballantyne and Routh in England and by many workers in this country. There remain many blanks in our knowledge of maternal syphilis, for instance, as to the degree of importance attaching to a negative Wassermann test in mother or new-born infant; and we have but little knowledge of the toxins of eclampsia apart from renal disease. Our knowledge of the causes of infantile death during parturition, apart from mechanical causes, and of the causes of death in the first week after live birth is still rudimentary. And this, notwithstanding the fact that pathological material is abundant and waiting for investigation. The difficulties of such investigation are great, but it is certain that in the coming years we shall have much light thrown on what is now obscure.

Meanwhile, it would be a calamity if the need for further investigation were to divert attention from the large scope for immediate reduction of mortality, both of mothers and infants, or to delay action; and in promoting this work, we have found in England that there is needed the active coöperation of every private medical practitioner, every midwife, voluntary hospitals, whether general or special, social workers, and public health authorities.

---

[2] Omitting cases among the coloured population, the percentage of syphilis was considerably lower

---

PROPOSED AMALGAMATION OF THE BRISTOL HOSPITALS.—The Bristol Royal Infirmary, the largest of the hospitals concerned, has decided by an almost unanimous vote at a largely attended governors' meeting to accept the proposed policy of hospital amalgamation. At this meeting the President, Mr. H. H. Wills, and the chairman of committee, Alderman F. Sheppard, recommended the adoption of this course, and explained the steps by which the movement towards amalgamation had progressed since its initiation in 1919. The only modification in the constitution of the "Joint Hospitals Council" proposed by the governors of the Royal Infirmary was an increase in the representation of labour interests. The other hospitals are still considering their attitude towards the proposal, and it is hoped that enough support will be forthcoming to give the scheme an early start.

SCURVY:

WITH SPECIAL REFERENCE TO PROPHYLAXIS IN THE ROYAL NAVY.[1]

BY P. W. BASSETT-SMITH, C.B., C.M.G., F.R.C.P.,
SURGEON-CAPTAIN, R.N.

THE subject of scurvy is of particular interest to all who have to maintain the health and well-being of our sailors.

Past History.

In the days of the old sailing ships, with voyages of extended duration, the danger of scurvy was much greater than it is now; little was known of the ætiology of the disease and catering difficulties were much more marked. Dr. Lind and Sir Gilbert Blane, the pioneers of naval hygiene, were both very active in studying and in endeavouring to eradicate this scourge of the navy. Fresh fruit and vegetables, as prophylactic and curative agents for scurvy, had been known to the Dutch as far back as 1564, and these had been successfully employed in the fleet by Sir Robert Hawkins in 1600, but the use of orange and lemon juice had been more or less forgotten until Dr. Lind insisted on their value. He, however, recommended *preserved* juice for use on long voyages. The fresh fruit juice was concentrated by heat to a thick syrup; as this was done in glazed earthenware vessels soluble lead salts were formed, and Lind drew attention to this danger, which he referred to as "death in the pot." Trotter strongly opposed the use of this form of preserved juice, as it was said to undergo fermentation and become mouldy. Unfortunately its issue to the crews in Cook's famous voyage of 1773–1774 did not prevent scurvy breaking out.

It was Gilbert Blane's teaching and powerful influence which brought Lind's recommendation into official use. Sir Gilbert Blane in 1757 pointed out the importance of cleanliness, sufficient ventilation, and absence of damp in ships, and the need of a supply of lemon juice for the prevention of scurvy. It was, however, not until 1796, when he was one of the Commissioners of the Navy Board, that the use of lemon juice was ordered as an essential part of the naval dietary, and this quickly resulted in the practical disappearance of scurvy from the Service afloat. In 1782 two-thirds of an ounce of lemon juice per man per diem protected the whole ship's company of H.M.S. *Suffolk* during a voyage of 23 weeks without touching port. In a discussion on the probable causes of the disease, which he attributed to the lack of a "certain element which is necessary for growth and repair," Blane foreshadowed the present deficiency theory.

From that time to the present lime juice has been a standing ration, but its efficacy has disappeared.

The reason for this has been ably shown by Mrs. Alice Henderson Smith. As originally prepared the lime juice was made from sweet limes, *Citrus medica*, with lemons, imported chiefly from Spain. In 1793 war stopped these supplies, but in 1802 delivery was resumed, and scurvy, which had obtained a temporary hold, was again almost eliminated. About 1860, by the development of the cultivation of limes in the West Indies, a large quantity was made available, and the contracts entered for the navy caused these, the sour lime, *Citrus medica var acida*, to supersede the sweet limes and lemons formerly in use, and for a time the new lime juice was believed to be better than the old. In Ross's polar expedition the original lemon juice had been issued, but Sir George Nares, in 1875, was provided with the new West Indian lime juice. The general conditions of the two expeditions were very similar, but while the former escaped scurvy, Sir George Nares's men suffered severely from it, in spite of the regular issue of the lime juice, thus demonstrating the failure of the new preparation as a prophylactic. The sister ship in the latter expedition, the *Investigator*, was supplied with lemon juice, and for 27 months after leaving home she had few cases, though the crew suffered great hardships. In three and a half years she had only three deaths from scurvy, whereas Nares had the same number in one year.

The evidence is clear that lemon juice is far more effective than lime juice in preventing scurvy, and this has been fully confirmed by the large number of laboratory experiments carried out at the Lister Institute, London, and elsewhere, which have determined exactly their relative values for the purpose. Lemon juice and sweet limes have therefore been found to repair a deficiency which, if not rectified, induces scurvy, and the consumption of these juices is curative for the same disease. This is in accordance with modern teaching, which attributes the condition to a deficiency of a certain accessory factor known as scurvy vitamine. This factor is found in living vegetable (and secondarily in animal) tissue; in largest amount in fresh fruit, green vegetables, and growing pulses, and, to a less extent, in roots and tubers. Young vegetables contain more than old. It is present in small amount in fresh meat and milk. It has not been found in yeast, fats, dry cereals, and pulses, but exists to a certain extent in canned tomatoes. The antiscurvy food factor is sensitive to high temperatures, and if exposed to them it rapidly loses its efficacy; the presence of alkali is also detrimental.

Recent History.

Much has been written of the prevalence of scurvy during and since the war among the combatant forces and in the civil populations chiefly affected in war areas. Of the former, those in Mesopotamia suffered very severely, and Colonel W. H. Willcox, in his excellent communications, has described the reasons for the outbreak very fully.

The high incidence amongst the native troops at Kut, in comparison with that of the Europeans, is explained on dietary grounds; the latter had fresh meat to supplement their meagre diet, and the former were more susceptible owing to diminished vitality from preventable causes. He states that the knowledge we then possessed for the prevention of scurvy and beri-beri was not fully appreciated and acted upon by those in authority—i.e., that the food must have the necessary accessory factors, as well as sufficient calories as estimated by the protein, carbohydrates, and fat. The fact that over 11,000 cases of scurvy occurred in the last six months of 1916 indicates the importance of the subject. The following table shows the amount of scurvy in the Indian troops and beri-beri in the British.

Year.	Scurvy (Indian).	Beri-beri (British).
1916	11,445	104
1917	2,197	84
1918	825	51

The crews of British men-of-war were also affected to a small extent, and as has been shown repeatedly by the endemic presence in the Persian Gulf of ship beri-beri, this is a question of some importance, more particularly in times of extra strain, as was the case in these years. Much has been done to prevent these outbreaks by increasing and supplementing the diet, but climatic conditions in that area always make the provision of efficient food-supplies difficult.

In other war areas, Serbia and the remainder of the Balkans, famine conditions have necessarily given rise to an enormous number of scurvy cases. In Northern Russia it is very prevalent each winter, particularly in the prisons. Even on the Western Front the cases of incipient scurvy were very numerous, due in great part to the use of tinned provisions. By Japanese investigators the conditions produced in guinea-pigs on a deficiency diet is considered to be similar to that found in ship beri-beri, a disease which undoubtedly links up human scurvy and beri.

The post-war hardships in the civil populations have also induced scurvy, and the gallant fight being made against this and other diseases by individuals of all classes and peoples throws a glimmer of sunshine on what is otherwise a dark and tempestuous horizon. The work in Vienna of Dr. Harriette Chick and others to ameliorate the sufferings of the infantile population is particularly noteworthy. From a scientific point of view such an overwhelming mass of cases has increased our knowledge of the clinical features of scurvy enormously, and many new facts have been ascertained.

Relationship of Scurvy to other Deficiency Diseases.

The ætiology, thanks to the work of British, American, French, and other observers, has now been placed on a sure foundation, following the elaborate investigations that have for years been carried out in establishing the ætiology of beri-beri as a deficiency disease. The close relationship of beri-beri, ship beri-beri, scurvy, and rickets was well shown in a diagram (Fig. 1) by Darling in 1915, which I here reproduce; it shows the gradation from polyneuritis avium at one end to that of rickets at the other. (Table I.)

---

[1] A paper read before the War Section of the Royal Society of Medicine on May 10th, 1920.

He recognised several varieties of beri beri—infantile beri beri, asylum beri beri, wet and dry beri beri (which Vedder and Clark look upon as distinct), the Brazilian type, endemic dropsy, and endemic peripheral neuritis Darling, with Surgeon General Gorgas, spent much time in investigating the endemic scurvy found among the native miners on the Rand in South Africa The cardiac condition resembled beri beri in the concentric hypertrophy of the right heart and degeneration of the vagus nerves The disease *appeared to depend upon the* following factors over milled corn as a chief article of diet, over cooked corn, over boiled meat, insufficient vegetables

Clinically, cases were seen of every degree of severity, from those who had spongy gums only to those with excessive hæmorrhages Some cases showed marked rickety symptoms, with extreme destruction of the chondro costal junctions, others were similar to beri beri with cardiac degeneration and changes in the vagus nerves Personal and racial factors had an unknown influence on the resultant symptoms A deficiency diet in a tropical African negro miner caused severe scurvy symptoms, and in a Cape Colony African labourer mild scurvy, a diet that in some African negroes caused scurvy, in others produced neuritis In all cases the knee-jerks were exaggerated (Those who have experience in ship beri beri have often been puzzled by the persistence of knee jerks in these cases also) The scurvy on the Rand, besides showing cardiac changes, differs from the ordinary forms found in time of poverty and famine in that it does not so readily yield to treatment

† Trop Dis Bull vol v, 1915 * Depending on age of patient

Darling sums up in the following words "The striking excentric hypertrophy and dilatation of the right heart, with extensive fatty degeneration of the muscle, and the severe degeneration of the vagus nerves, in cases of scurvy seen on the Rand, furnish new and additional facts which show the intimate relationship between scurvy and beri beri as to etiology The affinities between these two diseases and certain other cachexias lend emphasis to the opinion that they are all the result of the continued use of a one sided and deficient diet "

An Efficient, Portable, and Palatable Antiscorbutic

Recognising the antiscorbutic that cannot be supplied by the preserved lime juice from West Indian sources as at present made, it has been my object to provide an efficient, portable, and palatable substitute for the use of ships as occasion requires, and for such expeditions as may be undertaken in polar exploration, &c. For the last six months I have been experimenting at the R N. College, Greenwich, with guinea pigs, which are extremely susceptible to scurvy, to obtain such an antiscorbutic preparation to replace or add to the lime juice ration The value of these experiments with guinea pigs in relation to human scurvy has received abundant proof by experiments on monkeys carried out by Barnes and Hume, Chick, Hume and Skelton, and others

Much of the work done at Greenwich has not been original, but was nevertheless necessary before passing on to the methods of prevention and cure. The use of dried orange juice has been largely employed by Givens and McClugage, who found that in the fresh state it was equal to that of lemons, and that it retained its antiscurvy properties for a considerable time, but in their preparation the employment of a certain amount of heat diminishes the efficiency of the product In the investigation carried out at Greenwich various methods of preparing the juice were tried, evaporation at 60° C , de acidification, impregnation of filter paper, rapid drying, &c

Method of Preparation

The final laboratory method evolved, which has been continuously in use, is as follows —

The juice of fresh lemons is roughly filtered through muslin and then through filter paper under reduced pressure by means of a water pump The filtered juice is evaporated, in vacuo over sulphuric acid at ordinary temperature (13 5°-15 5° C) The residue of non crystallisable syrup is worked up into as stiff a paste as possible with a mixture of anhydrous lactose 97 per cent , gum tragacanth 3 per cent The paste is cut up into sections, each containing the juice of half a lemon These are rolled, faced with the mixture, and pressed to assume the *lozenge form* These tablets have been stored at 15°, 30°, and 37° C for months, and have been employed in the experiments The average yield of juice from one lemon is about 48 c cm , and each tablet contains the equivalent of 24 c cm of unfiltered juice The whole process takes about five days , no heat whatever is used

Experimental Results

Two series of experiments were carried out (Fig 2)

1 Using a basal diet of bran and oats, 60 c cm of milk heated in steam steriliser for 1½ hours, and water ad lib In this there was abundant water soluble anti beri beri, and fat soluble growth factor The control animals died between the thirtieth and fortieth day with all the usual signs of guinea pig scurvy and great loss of weight The addition of navy lime juice did not give any protection

FIG 2

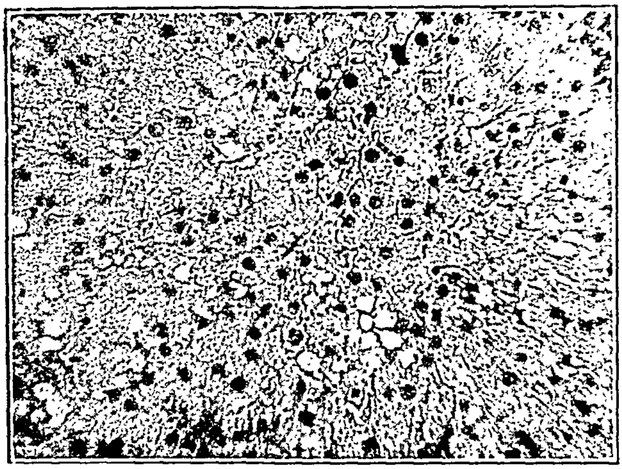
2. In the second series navy biscuit was used as the basal diet to which was added steamed milk 60 c.cm. and lime water; on one day per week the biscuit was substituted by oats to supply the anti-beri-beri vitamine. Growth was well maintained for over a fortnight, then the weight rapidly decreased, scurvy signs were manifested, and death followed. Control animals with 20 g. of fresh cabbage or 10 c.cm. fresh de-acidified lime juice grew normally. Animals were given 1/5 tablet (= 4·8 c.cm. fresh lemon juice), in solid form, by hand feeding. There was generally a loss of weight at first, but when they became accustomed to the diet the animals grew and remained healthy for over three months.

A further series was carried out to find the minimum amount of tablet which would act as a preventive dose. The daily amount was reduced to 1/10th (= 2·4 c.cm. fresh lemon juice). In two animals this was sufficient, but in two others signs of paralysis appeared, and they had to be placed on normal diet again; this was followed by recovery.

FIG 3.



Suprarenal gland in scurvy showing fatty degeneration. × 120.

Keeping properties.—Animals were also given tablets which had been stored for three months and more, and no loss of protective power was noticed. Tablets kept at 37° C. became dark in colour and softer, due to caramelisation of the lactose, and this appears to effect to a slight extent the vitamine properties. In no instance were the tablets found to have become mouldy, whether kept at room temperature or blood heat.

Average weight per 100 g. body-weight at time of death ... 87·9 mgm.

Six Normal Animals—Suprarenal Bodies.

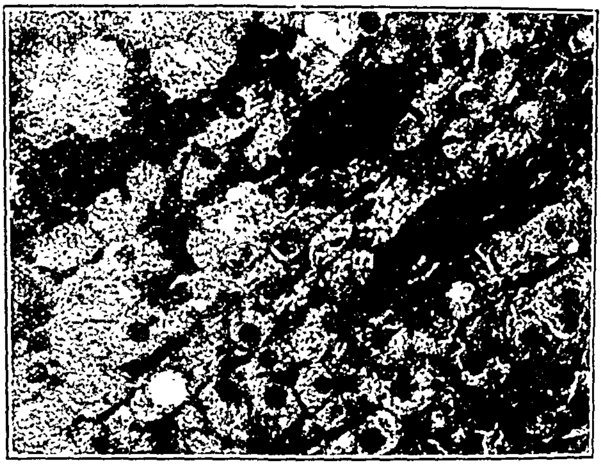
Average weight per 100 g. body-weight at time of death ... 25·8 mgm.

Therapeutic action.—If administered to an animal following scurvy signs, which were not too marked, a cure was effected, but if diarrhœa had set in, or a great loss of weight had occurred, the animals died.

As they have been so fully reported elsewhere, it is unnecessary to describe the scurvy symptoms in the animals or the post-mortem findings, but the condition of the suprarenal bodies, as emphasised by McCarrison, deserves further mention.

He has shown that in guinea-pigs these organs are enlarged, hæmorrhagic, and have a reduced adrenalin content, and with this there is a tendency to secondary bacterial blood infections (found once in my cases). In my experiments the changes in the suprarenals of the scorbutic animals were very marked. (Fig. 3 and 4.) There was marked congestion of the whole gland, with diffused or circumscribed hæmorrhages and fatty degeneration of the cells chiefly affecting the cortical areas. The weight of the glands was roughly three times that found in healthy guinea-pigs. The reduction of the normal secretion is, according to McCarrison, an early factor in the scurvy syndrome, and influences very markedly the metabolic changes in the animal, and he concluded that the evidence, so far available, points to the dependence of the functional perfection of the adrenal glands upon the adequate supply, in the food, of the accessory food factors of the various classes.

FIG. 4.



Another section showing circumscribed hæmorrhages in the cortical area. × 350.

Conclusions.

Many observations have shown that the onset of scurvy is very gradual. Dr. J. R. Comrie, in an account of scurvy in Russian prisons, stated that it might be 4½ months, but generally it is as long as 6 months, before symptoms are manifested. In the pre-scurvy stage, owing to the deprivation of antiscurvy factors, the metabolism of food is incomplete and a positive agent is added, which acts like a toxin, causing changes in the adrenals and their secretions, favouring the hæmorrhagic conditions which are such marked features of the declared disease.

The use of this concentrated preparation has shown that it has effective antiscurvy properties for animals. We may therefore, with confidence, apply its use to man under conditions of service which preclude the regular provision of fresh fruit and other known preventive substances. It could also be employed in the mercantile marine. Though it is not yet possible to say how long the activity of the retained antiscurvy vitamine will remain effective, it is probable that this will be of extended duration if the preparation is kept dry and cool. Dr. Chick, in Vienna, has found that 5 c.cm. of lemon juice is a prophylactic dose for infants, therefore 24 c.cm. would probably be ample for an adult (half a lemon). The tablets dissolve fairly readily if added to water containing a small quantity of bicarbonate of soda, and it is suggested that these dissolved tablets, containing antiscurvy accessory factor, should be added to the ordinary non-active pleasant-tasting lime juice at present issued.

For general service, when large quantities are required, the non-heated concentrated syrup, as obtained before being mixed with lactose, might be kept in bottles and the equivalent of 24 c.cm. of fresh lemon juice be given per man, after solution in water to which sugar has been added at the time of issue. It is probable that this syrup would keep without mould formation and this aspect is at present under consideration.

In this investigation I am greatly indebted to Mr. R. C. Frederick for his able assistance in preparing the tablets used, and to Sick-berth Steward A. Coules for his careful attention in feeding the animals.

A SHORT ACCOUNT OF AN OUTBREAK OF SMALL-POX IN OCCUPIED GERMANY.

BY G. G. JOHNSTONE, M.A., M.D., D.P.H. CAMB.,
CAPTAIN, R.A.M.C.(T.F.).

DURING the month of December, 1918, it will be recalled that the British Army of Occupation was moving through the Ardennes and the bleak and mountainous Eifel district on the way to take up its position along the Rhine. The Germans had, on the whole, been very successful in their rapid retreat, and beyond broken-down motor lorries and cars, and the frequent spectacle of a zone or border of discarded shrapnel helmets along each side of the roads at a distance of about 15 yards, there were few signs to show that the war had so recently ended. Inside some of the hospitals, however, there certainly were signs of blockage and overloading, and in the rush backwards in the case of the retreating army, and forwards in the case of the liberated prisoners of war, the German medical work must have been sorely taxed.

It happened, then, that in the Hospital of St. Vith—a little market town in the province (late German and now Belgian) of Malmedy—there was a case of small-pox in a Polish soldier, who had recently been demobilised from the German army. In the rush and pressure of the constant movement the diagnosis was not made until the infection had spread to other patients in the hospital. The Polish soldier himself was sent on an ambulance train across the Rhine undiagnosed. On the arrival of the first British troops at St. Vith the senior civilian local doctor reported that there was small-pox in the town. There were three cases in the local hospital and one in a house in the centre of the town. This latter case was being removed at once to the hospital. A car was immediately sent to Cologne—about 70 miles away across the mountains—to procure a supply of fresh lymph for use amongst the civilian population. The town was put out of bounds as a billeting area, and the column of troops—a brigade of cavalry and three whole infantry divisions—marched right through the town.

On investigation at the hospital it was found that the Polish soldier had been nursed in the same ward as a man who was suffering from pulmonary tuberculosis. The latter was frequently visited by a cousin—a midwife in practice in the town. The midwife was taken ill with small-pox in her own home on 30/11/18, a day or two after she had attended two confinements. On 15/12/18 her husband was removed to the hospital also suffering from small-pox. On each occasion after the removal of a case to the hospital the house was disinfected by the local authorities. The aged mother of the midwife (81 years) was removed to hospital at the same time as her daughter for the purpose of isolation. On 4/1/19 she was allowed to return to her home, which had been disinfected three weeks before, and on 18/1/19 she also contracted small-pox and was removed to the hospital, where she died. These were the only three cases occurring in the town of St. Vith, and all of them came from the same house.

Hospital Conditions.

A brief sketch of the local hospital will help to explain the cause of the incidence of other cases in this epidemic. On the outskirts of the town there was a building, or rather a composite group of buildings all within the same grounds. In these buildings were housed (1) the local hospital for general diseases; (2) a chapel; (3) an almshouse for aged people; (4) a small convent, the inmates of which were the nurses in the hospital; (5) a large orphanage and school of domestic economy. Here, then, we have a very suitable medium for the growth of a small-pox epidemic, and it seems almost surprising that the number of cases was not greater than actually did occur.

It has been already noted that a supply of lymph had been sent for from Cologne, and on 6/12/18 the inhabitants of the hospital and other buildings, and, as far as possible, of the town, were vaccinated by an organisation of the two local doctors and the Kreisarzt, or medical officer of health for the Kreis of Malmedy. In spite of vaccination, three nurses and one attendant were taken ill on 21/12/18. Two of the nurses, including the matron, died. Altogether five of the nursing staff of a total number of about 20 took the disease, and, in spite of vaccination both recent and remote, the type of the illness was grave. There was no proper isolation block in the hospital, and there was no small-pox hospital, or even proper infectious disease hospital for the district, so that the cases were isolated in a part of the building which was occupied by the aged pensioners, and below them by the nursing sisters.

It was not altogether surprising, then, that the incidence of cases amongst these aged people was very high. Eight (about two-thirds) of them were taken ill, and fortunately there was only one death. Their ages were respectively 40, 63, 75, 70, 72, 81, 52, and 70. At the time of the vaccination the authorities were rather of opinion that it was not essential to insist upon the vaccination of these aged folk, and thus five out of the eight had not been vaccinated since their childhood. Two of them were ill with bronchitis or influenza at the time, and it happened that the only fatal case was that of a woman who refused to be vaccinated in spite of advice.

In the same ward as that in which lay the original Polish soldier it has been mentioned that there was another patient—also a demobilised soldier of the German army. He took the disease, and before the diagnosis had been made he was frequently visited by: (1) his cousin, the midwife, already referred to; and (2) his father (aged 60), who lived in a village about 4½ miles away across the hills. This man was taken ill on 17/12/18 in his house, and as soon as the case had been diagnosed the whole of the population was vaccinated and the village was put out of bounds to British troops. The patient was removed to the St. Vith Hospital on 26/12/18. On 30/12/18 the mother and three children were all taken ill with the disease in a mild form in the hospital where they had been removed for isolation. They were vaccinated on 22/12/18. Fortunately, no other cases occurred in this village.

Vaccination Orders.

It was considered wise, however, by the British authorities that vaccination should be undertaken more extensively in the neighbouring villages. Many points had to be taken into consideration. St. Vith was the market town for that part of the country. Farmers, and others, were constantly coming in and going back to their isolated villages amongst the hills. No check had been made in the early days of visitors to the hospital. Owing to scarcity of civilian doctors and the long distances to be travelled, the poorer people did not seek medical advice unless an illness was of a severe or painful nature. Cases, then, of slight small-pox might lie ill in these villages for days and even weeks without isolation or any other precautions. Although the great majority of these villages were not in use at the moment as billeting areas for British troops, it was not known when the occasion for such use might suddenly arise. St. Vith was also a railway centre of some temporary importance, for it was here that many of the railway wagons and engines were collected from all parts of Germany and repaired previous to being sent over the border to France and Belgium under the terms of the armistice.

An order was then issued by the British military authorities that there should be a compulsory vaccination by the local German doctors of the inhabitants of the villages within seven miles of St. Vith. Lymph sufficient for 10,000 cases was supplied from Cologne to the Kreisarzt for the purpose of this vaccination, which took place during the middle of January.

Three Interesting Cases.

Three more cases remain to be noted, and they are all interesting in that they bring to light the weakness or inefficiency of the strict administration of the hospital as a small-pox isolation hospital.

The first case occurred in a remote village six miles from St. Vith. The husband of the patient had been in hospital and was discharged on 24/12/18. He took out with him some undisinfected clothing in a parcel. The parcel was not opened until 5/1/19. The woman was taken ill just about a fortnight later. She, with the rest of her family, had been vaccinated on 15/1/19, so that she was taken ill within five days of her vaccination. Owing to poverty and inaccessibility of the village a doctor was not called in until 10/2/19—that is, during the fourth week of the disease.

After the occurrence of this case orders were issued to the hospital and German medical officers that a complete list should be furnished of all patients who had left the hospital since the date of the first case, and that a weekly medical inspection of them should take place.

The next case brings out the above points even more clearly, for the patient—a man of 36—had been in the hospital suffering from morbus cordis, and had been nursed in an infected ward. He was discharged on 5/1/19 and he was taken ill about 10/1/19. No doctor was called in owing to poverty, and it was not until five weeks later—on 18/2/19—that the burgomaster of the village telephoned to another hospital and asked if the case could be admitted. The local doctor on his examination of the case noticed the marks of small-pox, and then, in consultation with a German doctor who had arrived from the interior of Germany to take charge of the epidemic, the history was elicited and the diagnosis made. The sister superior of the hospital had suspected that the patient was suffering from tuberculosis, and had fortunately put him in an isolation ward.

The village in which this case had occurred was again on the extreme northern periphery of the vaccination zone, so that a further zone was marked out, and the inhabitants of 11 more villages were all vaccinated. Fortunately this was the last case in this area.

The final case is just deserving of note. It occurred in Cologne itself. The patient had come from Cologne to St. Vith in search of work. He was given work in the hospital grounds and did odd jobs about the premises. After ten days or so he got tired of this and went back to Cologne without the knowledge of anybody. He was taken ill a few days later, but fortunately there were no contact cases.

When the casual nature of the administration of the hospital began to be more fully recognised a further order was issued by the British military authorities. This order forbade any civilian to leave the area of St. Vith without a certificate signed by a local German doctor, stating that the subject: (1) had been recently vaccinated; (2) was free from disease; (3) had not been in contact with a case of small-pox.

The above, then, is a short sketch of the epidemic. In all there were 30 cases, 4 of which died, and 3 of these 4 belonged to the nursing staff of the hospital.

Administrative Difficulties.

A few words may be added on the subject of administration, especially as the circumstances are rather exceptional. It should first be pointed out that in Prussia since 1874 the law has insisted on the vaccination of all children on two occasions: (1) during the first year of life, and (2) at puberty. Thus practically all the patients had been vaccinated at least twice, and some of them three and even four times. There was no real isolation hospital of any kind for this part of Germany. The Kreisarzt had urged the provision of one, but it was not until the British military authorities strengthened his hand by giving a direct order to the civilian authorities that any means for the isolation of small-pox cases and suspects were adequately provided. This took the form of temporary isolation huts in a field.

During the earlier days of the British occupation the civilian medical authorities undoubtedly were handicapped in their ability to take rapid and effective measures to cope with an epidemic. They were not allowed to use the telephone or telegraph. They were not allowed to use motor-cars. Their train service had come to a standstill. There was no petrol, and the great majority of cars were standing idle because there were no tyres. Circulation of civilians was greatly restricted. They were not allowed to use bicycles or to go out after dark. It was only a matter of a few days, however, before these orders were to a large extent rescinded in so far as they affected medical matters. Furthermore, the British authorities helped the local civilian authorities by the supply of disinfectants, petrol, and oil, and to a certain extent with transport to enable the epidemic to be more efficiently handled.

The population of the Kreis or Circle of Malmedy was between 30 and 40 thousand inhabitants, the majority of whom lived in small and straggling villages and hamlets scattered amongst the bleak hills of the Eifel district. For a part of the time the roads were covered with six inches of snow. This had the dual effect of isolating one village from another, and at the same time of preventing the efficient medical visitation and supervision of cases who were taken ill in the villages.

Here it may be mentioned that in these outlying villages there were cases of typhoid fever constantly being brought to medical notice far on in the course of the malady. They were just nursed at home by relatives, and their removal to hospital for better nursing and isolation was greatly resented in many cases. There was, apparently, no provision of any ambulance, motor or otherwise, for the removal of infectious or acute cases from their homes to the hospital, and, incidentally, it may be observed that one of the cases of small-pox—a man of 60 suffering from a grave confluent type of the disease—had to be removed in an open farm wagon a distance of 4½ miles across the hills by bad roads covered with six inches of snow. He fortunately recovered.

In conclusion, it is a pleasure to record the spirit of harmony which existed between the British military and the German civilian medical authorities with regard to steps which were taken to cope with the epidemic, and it is satisfactory to report that three British divisions and a cavalry brigade marched across this area during December without contracting a single case of the disease.

A REVIEW OF RECENT WORK ON THE
MORBID ANATOMY OF CHRONIC ARTHRITIS.[1]

BY G. L. KERR PRINGLE, *M.C.*, M.D. EDIN.,
HONORARY PHYSICIAN, ROYAL BATH HOSPITAL, HARROGATE.

THE pendulum is swinging back to the pre-Charcot days, when all forms of chronic arthritis were grouped under the one heading, and the differentiations brought forward by Charcot, Goldthwaite, and others must be considered as unsound from a pathological, ætiological, and even a clinical aspect.

As far back as 1906 this tendency can be seen in a paper published by Nathan, of New York; it is much emphasised by Daniel in his book on "Arthritis," published in 1912, and in a paper which I read before the Harrogate Medical Society in 1911 I urged the view that degenerative or osteo-arthritic changes followed in cases of long-standing rheumatoid arthritis. It is, however, the recent work of Nathan, published in the *American Journal of Medical Research* for 1917, which appears to me to remove all doubt on this perplexing subject.

Clinically there are two types of chronic arthritis, those which lead to ankylosis, both fibrous and osseous, and those which lead to ankylosis by deformity or locking. Pathologically there are also two types of chronic arthritis, the inflammations and the degenerations; but between these clinical and pathological types there are all gradations, and frequently both types are combined.

---

[1] A paper read at a discussion on Chronic Arthritis before the Harrogate Medical Society.

All these types may be produced by the same ætiological factor, the variations largely depending on the duration and intensity of the damaging agent, or as Nathan puts it —

> "The various anatomical and particularly the histological abnormalities, although characteristic in themselves, cannot be brought into correspondence with specific ætiological factors, clinical entities, or even definite pathological entities As there may be purely atrophic and purely proliferative conditions or combinations of the two in the joints of the same individual, and though there may be only synovial changes in some and only osseous changes in others, combinations of such changes are often to be found side by side in the different joints of the same individual"

Even in the cases of known ætiology the search for a specific reaction in the joint tissues in correspondence with specific morbid factors has been in vain.

Take, for example, tuberculosis We may have a distinctly synovial type with the formation of granulation pannus with secondary invasion of cartilage and bone, or we may have a primary osseous focus which invades the cartilage and joint cavity from the epiphysis The epiphyseal disease may present purely degenerative or purely inflammatory changes, or a combination of the two may be found on examination The changes may be accompanied by a proliferation in the joint interior resulting in fibrous or osseous ankylosis, or a focus may remain in the epiphysis causing atrophy of the neighbouring bone structures, which subsequently leads to deformation without involving the articular cartilage

Or, again, the statement by Daniel that "it may, on the other hand, well be that rheumatoid arthritis is the analogue of primary synovial tuberculosis, while osteoarthritis conforms more to the osseous infection, which *distinction does not make either a special entity but simply a clinical variety*"

Nathan has now been able to show by experiments on dogs that analogous phenomena occur in gonococcal, pneumococcal, streptococcal, and other infections The differences are simply in the extent and in the rapidity of the process, and not in the fundamental changes in the joint tissues

The Difficulties of Classification

It is impossible to discuss the many different classifications which have been made, but I shall give you one as an example to show how impossible it is to do so with any degree of accuracy

Goldthwaite divided the chronic joint conditions into atrophic, hypertrophic, and infectious, but this grouping, though convenient, is misleading and unscientific, as has been demonstrated by the admirable work of Nicholls and Richardson, who show that in the so-called atrophic type that the early predominating lesion is a proliferating process, while in the so called hypertrophic or degenerative type the early lesion is an inflammatory one It therefore becomes impossible to divide these joint diseases according to their pathological findings

There are no joint diseases which are exclusively degenerative or exclusively proliferative, the one or other may predominate in a particular joint, and there are evidences of both these conditions in practically all joint diseases All the phenomena of inflammation may be present, be followed by partial or complete resolution or by degenerative changes, again, when the inflammatory condition has long subsided, there may be simply degenerative changes with nothing to show that they were preceded by a more or less intense inflammatory condition The variations are due to the variations in the location, the intensity, the duration, the termination of the process, and the stage at which the affected structures are examined

To enable us to follow the various pathological manifestations intelligently it will be convenient to describe the morbid changes as they occur, first in the inflammatory and then in the degenerative stage, recollecting that they are differentiated for convenience, but that both processes take place to a certain degree in every joint affected with chronic arthritis

The Microscopic Structure of a Normal Joint

'In a normal joint a thin layer of cartilage covering the articulating surfaces of the bones is itself covered by a thin layer of specialised connective tissue, the perichondrium This layer is somewhat thickened at the periphery of *the joint, and becomes continuous with the connective* tissue of the *synovial membrane* Underneath the perichondrial layer the cartilage is hyaline and the cells are smaller and fewer in number than towards the epiphysis, where they occur in irregular groups, arranged at right angles to the joint surface, and are definitely encapsuled Between these vertical layers of cells are parallel bands of somewhat fibrous hyaline cartilage Beneath this layer comes a zone of provisional calcification (Nicholls and Richardson) which represents the line of transition from cartilage to bone, and may consist of a homogeneous, granular, or laminated matrix The cells are either cartilage cells sometimes surrounded by granular matrix, or true bone corpuscles surrounded by laminated lime bearing matrix Beneath this zone there is usually a continuous layer of bony tissue The marrow spaces just beneath the articular cartilage usually are vascular and lined at intervals by flattened endosteal cells, greatly enlarged, resembling the osteoblasts, occasionally bone giant cells, osteoclasts, are seen lying in little cut-out bays in the trabeculæ, which show lamination from the deposit of layers of calcified bone"

The dense fibrous joint capsule is lined with the mesenchymal cells of the synovial membrane, which commonly extends along the adjacent tendon sheaths At its junction with the periphery of the cartilage gradual *transition in type from fibrous into cartilaginous tissue can* be seen Thus we see that at the periphery of a joint the capsule, synovial membrane, perichondrium, and zone of provisional calcification become practically merged

When one remembers the embryonic origin of the joint structures the interpretation of many of the phenomena of joint diseases becomes much more easily understood The cells in the capsule, cartilage, periosteum, and area of transition between capsule, cartilage, and periosteum will, under morbid conditions or influences, proliferate and produce bone or cartilage in regions where these tissues are normally found *Under some circumstances, apparently, the cells proliferate as embryonic cells, and finally produce bone or cartilage in situations where these tissues are normally absent*

The Inflammatory Stage.

The focus of invasion commences as a subperiosteal inflammation in the region near the capsular insertion In a very short time this localised inflammation leads to localised periostitis In the milder cases the condition subsides at this stage, and the clinical phenomena of capsular irritation, joint effusion, and peri and para articular œdema disappear, and there remains a localised periosteal thickening or node as the only permanent change These are familiar to us all as Heberden's nodes When the disease is not arrested and advances from the periosteum to the capsule the inflammation gradually invades the joint cavity Hyperæmia is succeeded by the usual phenomena of inflammation, round celled infiltration, granulation, and connective tissue formation, leading to marked thickening of the capsule The most marked changes usually take place in the synovial membrane The proliferation of the synovial membrane produces a layer of granulation tissue, which, sooner or later, may extend over the cartilage as a thin pannus like layer

Nathan has experimentally on dogs produced a similar pannus by immobilising joints in plaster of Paris for periods of six weeks or so

If the source of irritation is removed the condition may stop there, but usually when the pannus comes in contact with the cartilage it produces a destruction and absorption of the cartilage by sending loops of blood vessels into it much in the same way as a catgut ligature is absorbed A proliferation of the perichondrium may, moreover, lead to the formation of a layer of specialised connective tissue, which readily transforms itself into cartilage and sometimes into bone When this process takes place in both articular cartilages the whole joint cavity may get filled up, adhesions take place between the two joint surfaces and the cartilages get absorbed and destroyed This proliferation is never regular, portions of cartilage are always left as small islands among the granulation tissue Nathan considers the above phenomena to be mainly synovial and refers to it as the synovial type

The osseous type —In addition to the changes already described within the joint cavity similar changes may take place (either independently or in conjunction with those already described) within the marrow of the epiphysis of the bone itself Lindsay Milne, writing in the *Journal of Pathology* for October, 1911, considers that this is the most common type, and that it always precedes the synovial

Just below the zone of provisional calcification a proliferation of the connective tissue of the marrow spaces of the epiphysis takes place, this is accompanied by the formation of blood vessels, which may extend upwards through the zone of provisional calcification, causing a destruction of the joint cartilage, and meet the granulation tissue of the pannus, if present. Radiograms will show that the bone is much rarefied, but rarefaction is also found in injuries where the joints have been kept at rest for some considerable period, and it has also been demonstrated in the bones of dogs by fixing the joints in plaster-of-Paris for some time. Further, there is very frequently an accompanying proliferation of the endosteum of the marrow spaces which may result in the formation of new bone or cartilage. If this process goes on in both bones of the articulation the whole joint cavity gets filled up, adhesions take place between the two joint surfaces, the cartilages become absorbed, and new bone is formed from the endosteum of the marrow spaces—with the result that eventually real osseous ankylosis occurs between the two bones of the articulation.

Nathan found that, besides the marrow changes, in the early stages of the epiphyseal involvement there is an intra- or para-articular joint exudation, which on investigation was always found to be sterile, whereas the streptococci could nearly always be demonstrated in the neighbouring epiphysis. So that in the early stages of joint infection the joint exudate may be considered symptomatic.

The end-results differ in every case and very frequently in different joints in the same individual. For instance, if the proliferation has been confined to the epiphysis, it may *remain as a focus in the epiphysis and not penetrate the line of provisional calcification*; there it produces softening and enlargement of the bone, which becomes much rarefied, and if the joint is used much, or forcibly moved, distortion is caused and subsequent atrophy of the neighbouring bone is seen, similar to that in tubercular epiphysitis.

All these joints may go on to degeneration, no matter what state the joint is in. The joint has received an injury which has caused more or less destruction of the articular surfaces or the epiphysis, and therefore, as in tubercle of old standing, trauma old and new, and faulty statics, degeneration may ensue.

The Stage of Degeneration.

If one wishes to see pure cases of degeneration he must examine the joints of some individual, preferably well up in years, who has been bedridden for a number of years. The primary change is a degeneration by fibrillation of the hyaline cartilage of the articulation, commencing with the disappearance of the spindle-celled perichondrium. As a result of the fibrillation the cartilage cells are set free, their capsules rupture, and they disintegrate and disappear. The depth to which the fibrillation extends varies in different parts of the same joint. At times, as a result of the fibrillation, minute masses of cartilage and fibrillated matrix are set free into the joint cavity. The underlying bone may thus become exposed, and, if the process continues, the two osseous surfaces may be in contact. Wherever erosion of cartilage occurs there is practically always a compensatory growth of cartilage or of bone of the opposite articular facet, so that the articular surface of the two bones of the joint are always in contact, and thus, as a result of the erosion of the cartilage of one bone and a corresponding overgrowth of cartilage due to proliferation of the perichondrium of the opposite articulating surface, the surface of the line of articulation becomes very irregular and indented. End-results of all these changes in the joint, which may take years in their production, are luxations and ankylosis by deformity or locking.

Further, since in this type of joint, change by destruction of the cartilage takes place slowly, and is at first confined to a portion of the joint surface only, motion of the joint continues for a long time. Under these circumstances it always happens that the articular surface of the joint, denuded of cartilage and still movable, undergoes marked thickening of the bone trabeculæ, and the marrow spaces of the articular ends of the bones may become completely obliterated. The X ray appearances show that the bone is very dense, and the exposed bone surface under friction from constant movement gets highly polished, and is known as eburnated bone.

Secondary changes take place in the shafts of the bones entering into the joint. These changes consist in an increase in the activity of the perichondrium at the periphery of the joint, and consequent new formation of cartilage which may be transformed into bone, causing an irregular and nodular increase in the size of the head of the bone and producing much deformity, known as "lipping," which is really not a degenerative, but a proliferative change. In those joints in which inflammation is followed by degeneration, or because of the loss of surface conformation, muscle shortening or capsular contraction, and motion is impossible, greatly impeded, or its resumption after the active process has subsided has been unduly delayed, the atrophy which appears during the early stages becomes more or less permanent.

The Association of Neurological with Arthritic Symptoms.

Finally, there are certain peculiarities characteristic of some forms of chronic arthritis which are apparently very difficult to bring into correlation with an infective origin. Nathan says that the peculiar deformations of the hands and fingers, the acroparæsthesia, and the premonitory weakness and spasm cannot be ascribed to the infectious focus within the joint at all. In many of these cases the symptoms simply indicate nerve irritation, or at most a perineuritis. Thus one case may show distinctly the characteristic contracture and trophic disturbance of an ulnar neuritis. In others the ulnar neuritis is complicated by the wrist drop of a radial neuritis; while in others one gets the peculiar deformity following a median neuritis.

The fact that there may be peripheral and central neural involvement also explains the changes in the skin, such as glossiness and ulceration of skin and nails, the œdema and the anomalies of sweat secretion so common in some of these cases. Nathan, in his experiments on dogs, found that in a large proportion of cases that the joints of the vertebral column were involved in the same way as those of the hand. That is to say, that in early cases of multiple chronic arthritis involving the joints of the hand and digits he also found identically the same processes going on in the spinal column. Hence he argues that when neurological symptoms are associated with arthritis it must be concluded that the spinal column is involved in the morbid process, and that the vertebral changes, consisting of endosteal and subperiosteal inflammation, have led to epidural and perispinal *exudation, causing root or slight spinal compression, which* may or may not be permanent. If his deductions are correct it explains why so many cases of polyarthritis present muscular atrophy and acroparæsthesias in the early stages and even in the pre-articular stages. In such cases no doubt the epidural surfaces of the vertebræ have become involved before the peripheral articulations.

Nathan's paper on "Polyarthritis and Spondylitis," published in the *American Journal of Medical Sciences* for 1916, is a most interesting and instructive one. Marked cases of spondylitis with definite osseous changes produce in some cases well-marked neural phenomena, which may or may not be associated with a polyarticular arthritis, but the diagnosis of endosteal or periosteal inflammation of the bones of the vertebral joints in its early stages at present seems to be almost an impossibility even with the X rays. Still, the fact that Nathan was able to produce by experiments on dogs changes in the vertebral joints identical with those which have been described in the human subject is a very strong argument in favour of his theory.

There are still other reasons for marked deformity; there are cases with deformity and complete dislocation of the phalanges, though the power is not much affected and the deformity does not correspond to peripheral or central nerve involvement, in which the radiograph shows no change in the bones. It was pointed out that the early stages of joint infection are characterised by intra- and peri-articular effusions, and in some cases the effusion is enormous. An effusion which reaches great proportions always leads to relaxation of the capsule and periarticular structures and, finally, to dislocation of the joints.

Conclusion.

Let me conclude this paper with a word of caution from Nathan. "Though it is not unlikely that a focus in a tooth is sometimes, and one in the tonsil is often, the point of entry for bacteria, it should be remembered that once the micro-organism has entered the blood its connexion with the portal of entry ceases. For this reason, though the removal of the affected teeth or tonsil will, if these are really the site of the original focus (which is not by any means always certain even when they are abnormal), prevent reinfection or recurrences, such proceedings have absolutely no influence upon the joint condition as it already exists. Moreover, it must be remembered that a focus in the joint structures, like a focus anywhere else, besides causing local changes, may be, and no doubt often is, a source of general infection and metastases."

LITERARY INTELLIGENCE.—A new set of Manuals for Medical Students is about to appear under the general heading of "The Students' Synopsis Series." The publishers, Messrs. J. and A. Churchill, announce the *immediate* issue of "Pharmacology," by Dr. Douglas Cow, and "Dentistry," by Mr. A. Bayford Underwood, while a "Synopsis of Surgery," by Mr. Ivor Back and Mr. A. Tudor Edwards, is in the press.

DR ALBERT ABRAMS'S
METHOD OF PERCUSSION
TO DELINEATE THE SOLID ORGANS IN THE CHEST AND ABDOMEN.

BY SIR JAMES BARR, M D GLASG , LL D LIVERP AND TORONTO

IN THE LANCET of March 6th there appeared a very interesting and instructive article by Dr Abrams on *Topographic Percussion and Visceral Tonicity*. This paper, I hope, will further elucidate some of the problems there set forth Dr Abrams reckons that in the ordinary run of diagnosis there are about 50 per cent of errors, and recently Dr Edmund I. Spriggs has followed in a similar strain In order to reduce those errors to a minimum Dr Abrams has introduced various novel methods of diagnosis, but in this communication I intend to confine my observations to the question of percussion Dr Abrams is, perhaps, doing more than anyone else in the present day to resuscitate the lost art of physical diagnosis, but he would be among the first to acknowledge that there is no individual or system infallible, and would, no doubt, agree with his countryman that "he who never made a mistake never made anything" All Dr Abrams s methods require an acute sense of hearing and a delicate sense of touch Those who are not thus endowed, or who are unwilling to take the trouble to cultivate those senses, need not waste their time in reading this paper

Dr Abrams's original description of "A New Method of Percussion" was very brief, only occupying about three octavo pages in large type It appeared in the *Medical Record* of Feb 16th, 1918, and was reprinted in *Physico Clinical Medicine* of December of the same year I have not seen any reference to the method in current medical literature, and I shall therefore deal with it somewhat in detail His article begins —

> "In percussion despite its antiquity and supreme clinical importance, it is difficult to eliminate the personal equation and the prejudiced preconception of perceiving what is expected to be perceived In dwelling on the deficiencies of this art the writer does so, not as a rebuke to the Herculean efforts made by traditional investigators, but to arraign our complacency, which accepts things as they are and views as a sacrilegist anyone who questions established methods "

Dr Abrams's Method of Mapping Out the Deep Cardiac Area

I shall begin with his method of mapping out the deep cardiac area, as that will form a good basis for what follows There are many physicians who honestly acknowledge that they are unable to percuss out the deep cardiac area, and question the ability of anyone else to do so There is at least one distinguished physician who sarcastically asks those who, he thinks, attempt the impossible, have you percussed the heart in systole or diastole? He seems to have forgotten that there is very little variation in the size of the heart on the whole during the various phases, and it occupies the same place during all its phases The superficial cardiac area is of no value, and many physicians who have the temerity to illustrate their writings with sketches of the deep areas merely portray their own ignorance It is surely, therefore, important that some serious attempt should be made to arrive at accuracy

In carrying out Abrams's method the patient should stand on a large aluminium or copper plate which has been earthed, and face due west It is convenient to have two plates, each of which need not be much larger than a large foot, as they can be placed widely apart, and in these observations it is important that the limbs should be well separated to prevent any risk of short circuiting For experimental work a single large square plate of at least four square feet in superfices is very useful as it can be placed so that the four sides will represent north, south, east, and west On a plate of this size the patient can be turned rapidly in any direction, and his feet kept widely apart, or brought close together as desired

There are many physicians who do not know the orientation of their own consulting rooms, and for such the acquisition of a compass is necessary At present in this country the magnetic meridian runs 16 degrees west of true north, which is rather less than a point and a half of the compass, for practical purposes this may be disregarded but if you wish to find the true north and west, &c , you have only to reckon a point and a half to the right of your compass bearings Of course there must be no magnetic material in the room sufficient to disturb your compass

When the patient is standing on the earthed plate or plates, facing due west, with arms held away from the sides and chest bared, you begin to mark out the left border of the heart You give a rapid series of brisk but gentle taps on the acromial end of the left clavicle with the middle finger of the right hand, at the same time you firmly draw the fore or middle finger of the left hand over the chest towards the heart, and as soon as this finger reaches the border of the heart there is a distinct change in the note of the percussion on the clavicle Moreover, if your finger be in an intercostal space you can distinctly feel the impact of the heart When you reach the point yielding dullness you can correct your observation by moving the skin back without altering the position of your finger on the latter, and you then get a clear resonant note Then bring your finger, with the skin, forward to the former position and the note again becomes dull These observations can and should be corroborated by the stethoscope, shifting the bell from without towards the heart, and once the border of the latter is reached you hear a distinct change in the percussion note The old wooden stethoscope is the best, but if for this work it is found to be inconvenient I use a small phonendoscope with a centre knob about five millimetres in diameter No one ever did or ever could become a skilful auscultator who uses that abominable spring contraption called a binaural stethoscope, sensitive ears could not bear such pressure and extraneous sounds for five minutes

Having marked out the left border with a dermatograph, you proceed in a similar manner to delineate the right border by percussing the acromial end of the right clavicle If you be ambidextrous you had better percuss with the left middle finger and use the right hand for delineating, there is, however, no difficulty in slightly changing your position so as to percuss with the right hand

The same method can be used for mapping out pleural effusion, lobar pneumonia, solid patches in the lung from any cause When the patient is earthed and facing west Dr Abrams has discovered specific areas of dullness in the chest and abdomen in certain diseases To take only one example, which can be easily verified In cases of cancer no matter where situated, when the patient is earthed as before directed, let him place his left hand on his right shoulder so as to pull the left scapula outwards and hold his right arm away from the body there will be found an oval area of *impaired percussion* about 3 in long by 2½ in wide in the left interscapular area Dr Abrams's figures, 7 by 5 cm , are rather less This can be easily mapped out with a stethoscope when percussing the acromial end of the left clavicle or more conveniently by his other method of direct percussion—viz , place the left forefinger on the chest, overlap it with the middle finger, and then percuss the terminal phalanx of the latter As the polarity of cancer is positive this dull area disappears when the patient faces south and returns when he again faces west

Another Method

There is another method of mapping out the deep cardiac area similar to that generally adopted in mapping the hollow organs such as the stomach and to which Pirera lays claim Place the bell of the stethoscope over the superficial cardiac area, draw your finger from without towards the heart, and when you have reached the border of the latter, or rather when you have somewhat overlapped it there is a distinct change of note, this is like percussing out a ledge underneath a table and is no more reliable The ease and accuracy with which you can mark out the ledge depends on the amount of support or, in other words, on the tone of the ledge and on the extent of the overlapping board In accuracy it is not comparable with Abrams s method The upper border of the liver can be determined either by the palpatory or auscultatory method with percussion of the acromial end of the right clavicle For the upper border of the spleen percuss the left clavicle

The lower border of the liver can be determined by the palpatory or auscultatory method, especially the latter, and percussing the right anterior superior iliac spine For the spleen percuss the left anterior superior iliac spine Both kidneys can be easily mapped out by the auscultatory method, and percussing the respective iliac spines The same methods can be used for mapping out growths in the abdomen

Unfortunately, patients cannot always stand up, nor is it always convenient to have them earthed and facing the west With patients lying in bed and without any particular regard to the points of the compass, I have successfully carried out Abrams s method, but in such circumstances I prefer a method which I introduced many years ago for locating a lobar pneumonia within the first six or 12 hours of its existence. Possibly I may be prejudiced because the method is my own. I lay the left hand with all the fingers spread out firmly on the chest so as to eliminate the vibrations of the chest walls; I then lightly percuss the middle finger and the slightest impairment in the resonance is easily detected, the lighter the percussion the more easy it is to determine differences in resonance. This method is applicable to the delineation of any organ in the chest or abdomen.

When I was engaged teaching students I used to show them how to palpate the deep cardiac area blindfolded, and then allow them to verify my palpation area by percussion. This is an exceedingly simple matter in children, and in any person with pliant costal cartilages. In all methods of percussion it is a good plan to shut your eyes as thus your hearing is in no way distracted, and as Abrams would say, you are less liable to hear simply what you expect to hear.

A NOTE ON

THE ERYTHROCYTES IN MALARIA.

BY ROBERT CRAIK, M.D. GLASG.

SOME years ago I saw a man in whose blood malignant rings were found, and noticed that, although infected corpuscles were not as numerous as 1 in 1000 reds, yet multiple infection of a disc with two or three parasites was not uncommon. Again, in 1916, in a soldier with benign tertians, a disc was seen with two parasites not infrequently. Segmentation in these two parasites occurs mainly in internal organs like the spleen, where choice of corpuscles may be restricted; but even so, in malignant tertian multiple infection is so conspicuous as to suggest lessened resistance in certain erythrocytes.

In this connexion it occurred to me that the action of lead might yield information. When lead is given, in health or in minor ailments, the blood film in most persons shows, in three to seven days, a few polychrome, polychrome punctated, and punctated reds. In a man of 22, with slight gleet but otherwise healthy, a film on the sixth day of administration showed no change. On the next day a distinct change was observed, and a count gave 4,800,000 reds and 8000 whites. While counting 100 whites there were seen 40 reds showing punctate basophilia—that is, 3200 per c.mm., or 1 in 1500 reds. On the following day these were increased—certainly 1 in 1000 reds. Beyond this there was little increase, and the lead was stopped on the twelfth day. There were usually as many polychrome as punctated reds. My impression is that punctated discs are always polychrome when they first appear.

There is general agreement that polychromasia means premature birth of the erythrocyte, and that punctate basophilia denotes something more pathological. Even in mild anæmia the former is seldom absent, whereas the latter is rarely present unless the anæmia is really serious. Only when punctate basophilia is seen in normal blood associated with but little polychromasia is it pathognomonic of lead poisoning. Thus lead enables one to turn into the circulation marked discs by which parasites may be traced.

Accordingly in two mild tertians, with infected corpuscles less than 1 in 500, and with practically normal blood, this mixture was given: Pb acetate 20 gr.; ac. acet. dil. ʒi.; aq. (distil.) chlorof. ad ℥viii., ℥ss. t.d.s. On the fourth day young rings were found in polychrome and in punctated discs. Young parasites occurred in normocytes also, and some marked discs were uninfected. Next day, as well as rings, amœboid and large pigmented forms were seen in punctated discs. This proves the life of a punctated disc to extend to two days at least. In polychrome or in polychrome punctated discs there were never seen any but young rings. This proves that within 24 hours the polychrome disc develops into a normocyte. In the same time a polychrome punctated becomes simply a punctated red. The fact that polychromes increase hardly at all after the first day is thus explained, for we may assume the daily output is about the same.

For the same reason we may infer that punctation is a transient phase in the life of an erythrocyte. And I suspect that a similar test with the quartan parasite would show that punctation disappears within 72 hours in approximately normal blood. Now these young, immature erythrocytes were in small numbers, about 2 in 1000 reds, yet the invading parasites, which were not numerous, readily found them. Multiple infection suggests that certain corpuscles are less resistant than others and the case in point indicates that these are the youngest corpuscles. Schüffner's dots were present in neither of these patients, but the dots should not be mistaken for punctate basophilia. The latter spots are blue-black and present in uninfected discs also; the dots are red, occur in infected discs only, and the smallest invading parasites are not associated with them. With median rings it is not easy to be sure whether a finely granular condition or a diffuse coppery rose (Wright) staining is the first stage. As the parasite ages red dots become distinct. In short, there is a basophil polychromasia and punctate basophilia on the one hand, and azurophil polychromasia and punctate azurophilia peculiar to the infected disc on the other.

Finally, in severe and prolonged malaria punctate basophilia often appears, but never apart from other signs (e.g., poikilocytosis, erythroblastosis) of serious anæmia. In such cases Schüffner's dots must have been encountered in the same film, but I am not aware that they have been seen in the same corpuscle with punctate basophilia. Possibly they are not so closely associated. The dots may only occur on invasion of mature corpuscles with full Hb complement. This would explain the absence of dots in most cases of benign tertian, the organism being less virulent or the corpuscles so resistant that only the youngest are vulnerable. And though infected cells are only 1 in 500 (= 10 c.cm. of blood destroyed in two days) the loss is confined to young cells and will lead to increase in the proportion of older cells—that is, to increase of death-rate. No doubt this will be met by erythrogenesis, but the result will be increase of less resistant cells, and this will play the game for the parasites.

Ealing, W.

ON THE CHOICE OF INDIVIDUALS FOR COLLIERY RESCUE WORK.

BY G. ARBOUR STEPHENS, M.D., B.S., B.SC. LOND.

As honorary medical officer of the Swansea Collieries Rescue Station I thought it advisable to make a medical examination of some of the men attending the practical classes held by Mr. Riddiford at the premises on the Strand. At these classes the men are trained to carry out various laborious exercises in a gallery that is filled with noxious fumes, and in order to do this they have to wear the oxygen apparatus under service conditions. With Mr. Riddiford's help I have examined over 50 men drawn from various collieries, and the conclusion I have arrived at is that the majority of the hearts are not first class. The table of results of this examination shows that the men who offer their services do so, not necessarily because they are strong and virile, but for other and varying motives.

The health-rate of the colliers is good, so that one would have expected a better class of man from the physical point of view, but the fact is that a large proportion of the men were "officials" of one grade or another. For rescue work one should have strong, active, healthy men, and if in the future the question of remuneration should arise, efficiency as well as proficiency must be considered. The following examples by way of illustration may be of interest:—

1. A man, aged 63, with thickened arteries and an abnormal heart, was considerably distressed after the practice. His age alone ought to have precluded him, but no doubt some element of "bravado" entered into his reasons for taking up the work.

2 One of 57 had a heart whose reserve power was much below normal

3 A man, aged 45, was upset after the practice and his heart was abnormal

4 The following, aged 47, 44, 41, 42 and 41, all had abnormal conditions of the heart

5 Only two of 40 years of age had satisfactory hearts but one of these had poor teeth

6 Several others had pyorrhœa so that obviously they were not in the best condition for combating adverse conditions Proper emphasis should be laid upon the mouth conditions of those who undertake rescue work

7 Four men were in a "nervy" condition, one of them had an irregularly beating heart, whilst another suffered from insomnia and had on one occasion lost his memory for three months

8 Smoking in several cases was indulged in to excess, with the result that men were not fit A, aged 37, smoked 4 ounces of shag per week and his heart was abnormal, B, aged 24, admitted to 3 packets of woodbines a day, which showed their effect on his heart, C smoked 2 ounces of shag a week and had an irregular heart Only one heavy smoker (and he smoked 40 cigarettes a day) had a good heart

Table of 50 Cases Showing Effects of Smoking Habits on the Heart

No	Age	Smoking habits	Condition of heart and remarks
1	30	10 cig a day	Mitral murmur
2	20	Non smoker	Toxic
3	21		Heart sounds weak
4	32	2 oz shag a week	Toxic (extra systoles)
5	57		Toxic
6	27	Non smoker	Very good
7	40*	15 cig a day	Toxic (pyorrhœa present)
8	29	10 ,,	Good
9	23*	Non smoker	Very good
10	25	40 cig a day	,
11	24	20 , ,,	Toxic
12	41	2½ oz a week	
13	40	Non smoker	Very good
14	42	Left off 6 weeks ago	Good
15	32	15 cig a day	Toxic (patient very nervous)
16	39		Very good
17	63	3 oz a week	Mitral murmur (thickened arteries)
18	30	Non smoker	Heart sounds feeble (patient had lost memory for 3 months)
19	24	15 cig a day	Toxic
20	38	Non smoker	Good
21	45		Fair (patient somewhat nervous)
22	47		Mitral murmur
23	31		Good
24	37	1 oz a week	Heart sounds weak
25	37	4 oz shag a week	Toxic
26	31	10 cig a day	Fairly good
27	34	Non smoker	Toxic (pyorrhœa present)
28	26	10 cig a day	Very good
29	28		
30	27	20 cig a day	Fair
31	22	Non smoker	Good
32	22		Toxic
33	27*	10 cig a day	Very good
34	26	Non smoker	Good
35	26	Heavy smoker	Heart irregular
36	30	20 cig a day	Toxic
37	39	20 ,, ,	Toxic (dyspnœa present)
38	39	10 ,	Heart sounds faint
39	26	10	Toxic (dyspnœa present)
40	32	7 , ,	Toxic rapid (bad teeth)
41	30	10 ,	Very good
42	44	10 ,	Toxic
43	37	15 ,	Toxic (bad teeth)
44	31	20 ,	Fair
45	44	10	Fair (pyorrhœa)
46	41	4 oz shag weekly	Very good
47	41		Fair
48	38		
49	33	10 cig a day	Toxic (patient nervous)
50	38	Occasional	Very good

* = ex army man

The term toxic I apply to a state of the heart produced by some toxin be it nicotine or any auto-intoxication estimated by means of what I call a cardioscope which consists of a bell receiver sufficiently large enough to cover the whole cardiac area With such an instrument the two sounds of the normal heart are equal whereas toxicity is shown by the marked shortening of the second sound

9 One man turned up who had not been to bed for 48 hours and consequently was not fit for practice, such thoughtlessness might prejudice the lives of those to be rescued

10 The three men who gave the best results were ex army men, one of whom had been in Gallipoli and the East for a long time

It is said that one volunteer is worth a dozen pressed men, but, as a result of my examination, I cannot agree with that statement If this duty of rescue has to be done it must be done well, and undertaken by those men who are in a sound physical condition

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL

PERFECT DENTITION IN OLD AGE

By J O Butcher L D S R C S Eng

THE photographs are from casts taken of the mouth of a woman, aged 84 years In my experience this condition is unique The missing molar 7| I removed under nitrous oxide about two years ago at the age of 82 years, and I regret I could not procure models previous to that operation Two or three of the superior incisors have been filled on the labial surface, and one or two other fillings can be seen in the photographs, otherwise the teeth are all strong and extremely well formed, and are more than efficient for the need of a person of such advanced age The patient is blind from cataract, and suffered from a severe attack of typhoid at 18 years of age, and scarlet fever at 11 years She is very moderate in diet Both parents are said to have had exceptionally good teeth

Cast of the mouth of a woman of 84 with 31 good strong teeth, the arrows mark the median plane A, photograph taken from left side

B photograph taken from the right side the right upper middle molar has been extracted

Harley street, W

HYSTERICAL PARALYSIS IN A BOY.

By J. Arthur Gorsky, L M S S A,

HOUSE PHYSICIAN WESTMINSTER HOSPITAL

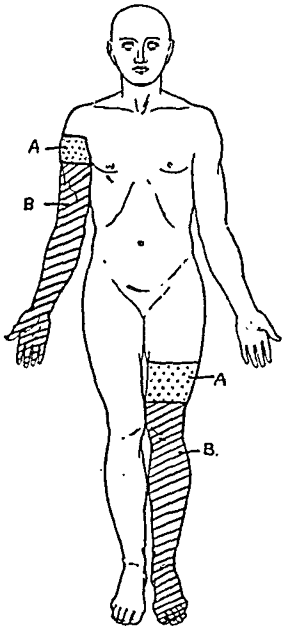
THIS case appears worth recording because of the sudden cure after a long illness

The patient a boy scout, aged 14 years was taken ill four months ago with very severe headache after returning from a cinema He remained in bed for several weeks and early in 1920 was admitted to a London hospital for two weeks where a diagnosis of meningitis was said to have been made At the end of this period he was sent to a convalescent home for a further three weeks, when he returned home he was found to have total paralysis of the right arm and left leg He had in addition become deaf, especially in the right ear, and partially blind, the symptoms being most marked in the right eye. The boy had no elevation of temperature, and there was no history of vomiting. During the last two or three weeks of February, 1920, the patient had numerous convulsive attacks, with violent twitchings of the head and limbs, and it is stated that three people were required to hold him down. During these attacks there was no loss of consciousness, and the boy was able to reply to questions. He neither bit his tongue nor passed urine during them.

During the week before admission to Westminster Hospital he had attacks of barking like a dog, lasting a quarter to a half hour at a time, and audible several doors away along the street. Sometimes, it is stated, he snapped at bystanders.

The patient was seen by Sir James Purves Stewart, senior physician to Westminster Hospital, who recognised the condition as hysteria, and the patient was admitted on March 4th to hospital for treatment. It is interesting to note that the diagnosis made previous to admission had been "tumour and meningitis at the base of the brain." He had been watched assiduously by his mother and benevolent lady visitors, and was also frequently visited by his spiritual adviser to soothe his dying moments.

Examination by Sir James Purves Stewart, March 5th, 1920.—He appeared an intelligent boy with normal speech and articulation. When shown a printed card and asked to read it he said he could not understand it. When spoken to he appeared deaf in the right ear and placed his hand to the left ear; nevertheless, later on, when told in an undertone to put out his tongue, he did so. The optic discs, pupils, and cranial nerves were normal. To cotton-wool touches there was anæsthesia of the right upper limb up to a horizontal line an inch below the acromial process, and of the left lower limb up to an inch below the middle of thigh. To pin-pricks there was analgesia up to a level of 3 inches below that of the cotton-wool anæsthesia. (See diagram.) The patient had apparent loss of joint-sense in the right fingers and elbow, and in the left foot and knee. With the eyes closed the "Yes-No" test was successful—i.e., the patient said "Yes" every time he was touched on the normal aspects of the body, and "No" on the anæsthetic areas. The right upper limb was much feebler than the left, but he could execute movements at all joints. (When previously examined on March 2nd and 4th the right arm was flaccid and totally paralysed.) The left lower limb was feebler than the right, but no individual movement was impossible in bed. He could raise it against slight resistance.



A = cotton-wool anæsthesia.
B = pin-prick anæsthesia.

Gait.—He could not stand or walk alone, and wriggled violently with trunk and limbs when supported on both sides. The supinator-jerks, knee-jerks, and ankle-jerks were brisk and equal. There was no ankle-clonus and the plantar reflexes were flexor. The cremasteric reflexes were normal, and the abdominal reflexes were equal and normal. Within a few minutes after the foregoing examination, by dint of encouragement and suggestion, the patient became able to walk alone, at first with difficulty, tending to cross his feet in a zig-zag fashion. Later he walked quite normally, and was then able to hop alternately, first on one leg and then on the other. After a few minutes' practice with a faradic battery, gradually diminishing in strength, the patient lost his anæsthesia and analgesia. He still remained partially blind and deaf. The patient was therefore taken up to the electrical department (he ran upstairs quite well), where Dr. E. S. Worrall applied the galvanic current to his temporal regions. The patient noticed the normal flash passing across his eyes as the current was reversed. Prior to this he was unable to read a printed card placed in front of him, but following the flash he was able to read perfectly. The hysterical deafness was promptly cured by the application of high-frequency tubes to his ears.

The interesting feature of the case is that although ill for four months the patient was cured within a few minutes after the examination and three days later he left hospital for a holiday at Weymouth.

I am deeply indebted to Sir James Purves Stewart for his kindness in allowing me to publish the notes of this case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

WAR SECTION.

SCURVY.

A MEETING of this section of the Royal Society of Medicine was held on May 10th, when a paper on Scurvy was read by Surgeon-Captain P. W. BASSETT-SMITH, R.N., which appears in another column. In the short discussion which followed,

Major-General Sir WILLIAM GRANT MACPHERSON said that scurvy in Mesopotamia, notwithstanding the observations of Colonel W. H. Willcox, was not altogether due to want of recognition of its causes, but to the impossibility of getting fresh vegetables and other foods to troops operating in certain areas. These foods went bad in consequence of climatic conditions before reaching the troops, and it was these troops which suffered most. As regarded the resemblance between scurvy and beri-beri, this was pointed out by himself in a report which was published in the official reports of the Russo-Japanese war. He had observed thousands of cases of beri-beri amongst the Japanese in Manchuria in 1904 and 1905, followed by some 20,000 cases of scurvy amongst the Russians in Port Arthur, and the resemblance between the two diseases in their clinical aspects was so marked as to form the subject of a special report. The cause of beri-beri amongst the Japanese was the use of highly milled and over-cooked rice as the chief ration, and that of scurvy amongst the Russians the almost entire absence of fresh food and vegetables during the siege of Port Arthur.

Colonel C. J. MARTIN thought it established that the varieties of antiscorbutic substances or vitamines present in different foodstuffs varied greatly in their reaction to and destructibility by heat. He considered that fresh meat, if not over-cooked, was an extremely valuable antiscorbutic, and that orange-juice could stand prolonged heating without losing its antiscorbutic properties, while cabbage very rapidly lost these properties after boiling.

Colonel S. L. CUMMINS congratulated Surgeon-Captain Bassett-Smith on his valuable contribution to the practical as compared with the purely theoretical aspects of the prophylaxis of scurvy, and considered that both services were highly indebted to him for his labours in the preparation of a suitable antiscorbutic in such a portable, efficient, and convenient form as the lozenges he had exhibited to the meeting.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS.

ANNUAL GENERAL MEETING.—EXHIBITION OF CASES.

THE annual general meeting of this section of the Royal Society of Medicine was held on May 4th, Mr. E. MUIRHEAD LITTLE, the President, being in the chair.

Mr. LAMING EVANS showed radiograms of a case of Dislocation of the Hips, Knees, Ankles, and Radii. As the patient was unable to be present the case will be shown at a meeting of the section next session.

Mr. C. J. MARSHALL showed a case of

Genu Varum of Late Onset.

The patient was a youth of 18 years. Nothing abnormal was noticed until a year ago, and little change occurred until six months ago, since when the condition had been growing rapidly worse. The general health had been otherwise good and there was no history of previous illness. The parents stated that the patient was markedly inferior to his brothers in height and general build. He was a sallow, greasy-skinned youth, about 5 feet 4 inches in height. The lower limbs showed severe genu varum, the knees being 5 inches apart, with the malleoli in contact. The curvature was more marked on the left side. In each limb the femur and tibia shared in the deformity, the tibia showing the greater change. Above the inner condyles of the femora a small expansion of the bone could be felt at the level of the epiphyseal cartilage. There was no such change in the tibiæ The lower ends of the radii and ulnæ seemed expanded, and the radial styloid process was lower than usual Severe gingivitis was present The spleen was slightly tender and descended to two fingers' breadths below the ribs on inspiration *The glands and joints showed nothing abnormal The Wassermann reaction was negative Except for a leucocytosis of 21,000, the blood was normal* Radiograms showed changes in the bones concerned, which were fairly typical of rickets The epiphyseal interval was increased, and the adjoining parts of the diaphyses and epiphyses showed rarefaction

In the case of the femora the softened tissue projected on the inner side Both in the femora and in the tibiæ these changes affected *only the inner aspect of the epiphyseal regions* On the outer sides fusion of epiphysis and diaphysis seemed already to have taken place At the wrists identical changes were present at the epiphyseal lines in their entirety There was apparently delayed growth of the ulnæ, the line lying much higher than that of the radius In addition, the line in the radius was directed obliquely downwards and to the radial side

Mr Marshall considered that the feature of the case chiefly meriting attention was the curious selective action of the pathological process at the epiphyses in the knee region Accepting the process as essentially the same as rickets, we were confronted with the question of late rickets or continued rickets If the latter, why had fusion occurred already on one side of the epiphyses two years in advance of the usual date? The therapeutic test would decide whether *the gingivitis was the source of infection There might possibly, in addition, be some glandular deficiency* There was no evidence to place the case in the category of "nephritis associated with deformities at the knees" described in THE LANCET of Jan 3rd last

The treatment he proposed to adopt was attention to general hygiene, dental toilet, thyroid feeding for a time, and gradual correction of the deformity by screw pressure on metal plates embedded in plaster cases, gripping thighs and legs After a suitable period of recumbency, sufficient to procure correction, he would order the wearing of knee splints with moulded thigh and calf pieces, and irons to the ankles

Mr R C ELMSLIE said that in late, continued, or recrudescent rickets, *there were more characteristic changes than in this boy Possibly the changes in* bones which are called "rickety" were not always due to the same cause He had met with the same changes in renal disease and had seen cases of intestinal infantilism which had all the appearance of rickets In this case the changes were like those of rickets, and were probably due to sepsis He would give such food as we knew from our experience of rickets would assist ossification

Mr ELMSLIE showed a case of

Paralytic Dislocation of the Hip

It was that of a boy, aged 15, who had had infantile paralysis as a baby The right lower limb was now affected and was 3 inches shorter than the left The muscles around the hip were fairly strong, and all groups appeared to be active The thigh muscles were normal, but below the knee the tibialis anticus was powerless, the remainder of the anterior tibial group being unaffected The calf muscles were paralysed, with the exception of the long flexors of the toes Talipes calcaneo valgus was present There was a scar on the outer side of the foot, but Mr Elmslie *did not* know what operation had been performed The hip was dislocated, the head of the femur being palpable at the level of the anterior superior iliac spine, the femoral neck was apparently much anteverted X ray examination showed that the femoral head was well formed but the acetabulum was shallow, and its upper margin was much flattened

The PRESIDENT suggested that the case might be one of congenital dislocation, poliomyelitis occurring subsequently As all the groups of muscles around the hip joint were active, he thought *that the* paralysis could not have produced the dislocation

Ankylosis

Mr P. B ROTH showed two cases of Ankylosis

The first was that of a woman, aged 43 years, with bony ankylosis of the left knee In May, 1919, after some kneeling, the left knee began to swell and became hot and painful Cold dressings were applied and improvement followed, but not recovery She spent five months in bed, and treatment by Scott's dressing and splinting was carried out No operation of any kind was performed In March, 1920, she came to hospital complaining of stiffness of the left knee and swelling of the right ankle, the swelling coming on at night and subsiding by the morning On examination there was complete bony ankylosis of the left knee, which, fortunately, had occurred in the extended position There was slight heat and swelling of the right ankle The pupils were unequal, there was severe pyorrhœa, the Wassermann reaction was negative As X ray examination of the right ankle suggested gonorrhœa, treatment by gonococcal vaccine had been started

The second case was one of bony ankylosis of the right ankle-joint in a woman aged 42 After having given birth to six healthy children, all of whom were alive and well, there was one premature birth at six or seven months, followed by two miscarriages Shortly after the last miscarriage some ulceration appeared round the right ankle, and an abscess formed in the left buttock The right foot had become dropped, and for this a splint was applied for six weeks, but no improvement followed When seen in May, 1919, there was complete bony ankylosis of the right ankle joint with the foot fully plantar flexed As the patient was unable to walk owing to the position of the foot, an anterior cuneiform osteotomy was done in October, 1919, and the foot brought up to a right angle Bony ankylosis had again formed, but, with the foot in that position, the patient was able to get about comfortably

Mr H A T FAIRBANK showed a case of

Bilateral Congenital Elevation of the Shoulder

The patient was a girl aged 10 years and the mother had noticed that she could not raise the arm properly only two months ago Both scapulæ lay at an abnormally high level, the right being higher than the left Both were rather small, and that on the right had the vertebral border tilted up On both sides the movements of these bones were much restricted, the vertebral border hardly moved at all from the spine, yet the left arm could be raised to the vertical, whilst the right only moved to a position a little beyond right angle abduction The spinal column was flattened in the upper dorsal region, and there was a slight long dorsal curve to the right Complete electrical examination of scapular muscles had not yet been carried out A radiogram showed the presence of 13 ribs on each side, the highest being well formed and apparently a normal first rib on each side The fifth, sixth, and seventh dorsal bodies, reckoning all ribs as bone ribs, seemed to be flattened and crowded together Considering the malposition of the scapulæ and the extra ribs, the vertebral deformity was considered to be congenital and not the result of disease No treatment was considered necessary

Mr ROTH read a note on

Abnormal Torsion of the Femoral Shaft

At a recent meeting of the section he had shown a small child with waddling gait of unknown origin, and Dr Martin Berry had suggested that it was a case of abnormal torsion of the femoral shaft His paper was an account of a newly published work by Professor Karl Pearson entitled "A Study of the Long Bones of the English Skeleton"[1] He (Mr Roth) thought that some particulars of the condition might be of interest to members of the section

1 *Normal torsion of the shaft* —There exists in the normal femur a torsion or twist of the shaft If the upper end be regarded as fixed the torsion consists of a rotation inwards of the lower end This torsion affects the whole of the shaft It is much more marked in the left femur than in the right, and slightly more marked in the female than in the male Thus in 735 femora measured, of which 359 were right and 376 left, the average angle of torsion for the former was 21 8° and for the latter 27 7° Of the 359 right, of which 208 were males and 151 females, the average angle for the former was 21 7°, and for the latter 22 0° Of the 376 left, of which 211 were males and 165 females, the average angle for the former was 26 7 , and for the latter 28 7° The largest angle recorded was 69 6°

2 *Measurement of the torsion* —To measure the amount of torsion a torsiometer was devised for use with the detached femur

3 *Abnormal torsion of the shaft* —When the lower end of the femur is rotated inwards the torsion is known as *positive torsion* when the lower end of the femur is rotated outwards it is known as *negative torsion* Mr Roth suggested that marked *negative torsion could certainly give rise to symptoms, and he considered his case* of the child with waddling gait as an example of the condition Of the 735 femora examined by Professor Karl Pearson and his co workers negative torsion was present in 13 cases or 1 76 per cent, the average negative angle being 8 7° In six of the cases there was deformity of the shaft suggestive of rickets

4 *Recognition of abnormal (negative) torsion in the living subject* —His case showed the following features (1) the presence of rickets, (2) waddling gait, (3) rotation of the thighs outwards, so that when the child walked the two feet

---

[1] Reviewed in THE LANCET May 15th

enclosed an angle of 90°; (4) no demonstrable radiographic abnormality; (5) when supine on a flat surface, with the feet touching and toes pointing directly upwards, the great trochanter occupied a more anterior position than normal. The *normal position for the trochanter* with the patient in this position was exactly midway between the surface of the table and the upper surface of the thigh. In an older subject it might be possible to demonstrate the condition radiographically. The small trochanter ossifies at 12 or 13 years, and in the position described above, if negative torsion be present, the trochanter will be twisted out of sight.

5. *Treatment.*—The child must be taught to walk with its feet pointing straight forwards. If after several years of instruction and supervision the waddling gait persisted, there appeared no alternative to an osteotomy of the femur, with rotation inwards of the lower fragment for the number of degrees, and fixation in plaster.

An interesting point was Professor Pearson's discovery that the left femur was normally much more twisted than the right. One would have expected that the right foot would be more turned out than the left, but Mr. Roth said that he knew of no observations confirming this. It had been suggested to him that this might be why a blind-folded person set to walk straight across an open space walked in a circle. The cause of the condition he supposed to be a rickety softening of the bones. When one lay on one's back there was always unconscious rotation outwards of the thighs, due to gravity, and in a rickety child this rotation affected the growing architecture of the bones.

SECTION OF LARYNGOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on May 7th, Dr. A. **BROWN KELLY** occupying the chair.

Caseous Rhinitis.

Dr. **DAN MCKENZIE** showed a man, aged 61, the subject of Caseous Rhinitis.

His complaint was of nasal obstruction—on the right side for four months, on the left for two weeks. Two months of pain in the right supra-orbital region was relieved by epistaxis two weeks before the exhibitor saw him. There was an ill-defined swelling of the right cheek and some bulging of the superior maxilla. Since the onset the patient had become 2 st. lighter, and there was a foul discharge from the nose. There was a fleshy growth in the nose, bulging from the ethmoidal region on both sides. It looked like the malignant growth some had suggested. On trying to secure a portion for microscopy its nature was revealed, and its evacuation by syringing and curetting was commenced, but was not complete until six months had elapsed. A large perforation remained in the ethmoidal septum, and most of both ethmoidal labyrinths had disappeared. He could not find out anything about the pathogenesis of the condition. The caseous material was composed only of amorphous granular lipoids swarming with bacteria.

Dr. W. H. **KELSON** spoke of a case he showed in 1904. Though this condition looked like malignant disease, it did well when treated and recurrence was very rare. In his case staphylococci and Klebs-Löffler bacilli were found.—Mr. W. **STUART-LOW** remarked on the comparative rarity of these cases in later years. He thought the condition was due to pressure.—Mr. **NORMAN PATTERSON** referred to two cases in which caseous rhinitis was associated with malignant disease, and the diagnosis in the first instance was caseous rhinitis.—Mr. A. **RYLAND** said that in a case of his own the antero-meatal wall was broken down, and there was limited ethmoid disease in the nose. One patient had an ethmoid polyp, and he got her to blow down the nose, when she evacuated a large quantity of caseous material. The tip of his little finger went easily into the antrum. The report on the evacuated material was streptothrix in abundance, with other micro-organisms.—Mr. F. **SPICER** referred to a case in a man, aged 70, in whom the condition recurred five or six times.—The **CHAIRMAN** referred to 12 cases he had seen, but none so marked as that now shown. In one he diagnosed malignant disease, owing to bulging inwards of the antral wall and the amount of tissue present. Rhinitis caseosa was not a morbid entity, but the name served to indicate a condition in which, owing to mechanical causes, secretion was bottled up, became stagnant, and underwent chemical and physical changes. A foreign body might be present, but stagnation might occur in one of the accessory sinuses or cavities. He described several of his cases. Thorough ventilation and drainage of the aperture seemed to end the trouble.—Dr. G. W. **HILL** said that in the ten cases of the condition he has seen there was generally some obvious origin; in three there was necrosed bone, two were syphilitic. He referred to an operation for the condition which he did on a valuable horse.—Dr. J. **DUNDAS GRANT** agreed that the cause was generally some mechanical obstruction. In some the shape of the turbinate body favoured obstruction, and the presence of a slight cause of inflammation precipitated the condition. In one case he found a piece of blotting-paper.

Other Cases.

Dr. **DAN MCKENZIE** exhibited a case of Dental Abscess of the Nasal Septum. The patient, aged 19, a week before coming to hospital developed an alveolar abscess in connexion with the root of the right upper lateral incisor. A few days later it broke, but the nose became completely blocked. Pus could be squeezed down from the nose into the mouth, where it emerged from the opening in the gum. There was no history of trauma.

Mr. **FRANK A. ROSE** showed a Tooth which he removed from a right secondary bronchus. A skiagram was also exhibited.—Dr. **IRWIN MOORE** congratulated Mr. Rose on his success. An important feature was the removal by the per oral method. He referred to cases in which attempts to remove a foreign body from the same situation had been very difficult and failed more than once. This accident appeared to be common in America, but there were very few cases recorded in this country, from which it was reasonable to infer that our dental surgeons exercised great skill and care.

Mr. T. B. **LAYTON** showed a case of Frontal Sinusitis. The patient had a swelling of the right orbit, with diplopia. No pus was seen in the nasal fossa, but the mucous membrane covering the middle turbinal was œdematous and polypoid. At the operation a cavity the size of a duck's egg was found occupying the site of the frontal and anterior ethmoidal air cells. It contained polypoid masses of mucous membrane, which were scraped away. The patient was progressing, but was not yet well.—Dr. P. **WATSON-WILLIAMS** commented on the slight deformity with such a large cavity. The notes led him to regard the case rather as one of mucocele than sinusitis.

Mr. **NORMAN PATTERSON** and Dr. **NORMAN H. PIKE** showed a patient, a woman aged 45, with a Supraglottic Tumour. For five or six years she had had trouble with her voice, which was weak and toneless; there was also some difficulty in swallowing. She had lost 2 st. in weight.—Mr. W. H. **JEWELL** thought it was a cyst of the epiglottis.—Mr. **STUART-LOW** advocated persistent galvano-cautery puncture.—Mr. **CYRIL HORSFORD** did not think the galvano-cautery would cure the condition.

Dr. **IRWIN MOORE** showed a boy, aged 16, who was the subject of Left Frontal Sinus Suppuration, and on whom the Killian operation was performed. Following a cold, a temperature of 105°F. was developed, with severe pain over the left eye and temporal region. There was no purulent discharge from the nose, but he had a severe hæmorrhage from the left side. On opening the left frontal sinus, which was full of pus, no connexion with the external abscess could be traced. The right frontal sinus was healthy. The rapid recovery the exhibitor attributed to the use of B.I.P.

Mr. W. **DOUGLAS HARMER** showed a baby with a depressed bridge of the nose. Skiagrams showed no evidence of destruction or fracture; there was no rash nor enlargement of spleen, and the Wassermann test in both mother and child was negative. The general view expressed was that despite the negative Wassermann the case was syphilitic, and hyd. cum creta was recommended.

Mr. G. W. **BADGEROW** showed a patient with a laryngeal condition for diagnosis, and suggestions as to treatment. For two years the slightest exertion resulted in difficulty in breathing. Two stones were said to have been lost in weight in three months. No tubercle bacilli were detected in the sputum, and skiagrams showed no signs of aneurysm or neoplasm. The vocal cords were fixed and red, and the ventricular bands œdematous.—Dr. **WATSON-WILLIAMS** did not consider a negative Wassermann as of conclusive value, and suggested anti-syphilitic treatment.

Mr. **L. COLLEDGE** exhibited a case of Laryngeal Tuberculosis in a patient who worked in a very dusty atmosphere. There was a small subglottic swelling below the anterior commissure, and some injection of the vocal cords.—The case was discussed by Mr. **HORSFORD**, Mr. **STUART-LOW**, Mr. **J. F. O'MALLEY**, Dr. **DUNDAS GRANT**, and others.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM: ANNUAL CONGRESS.

THE Annual Congress of this society took place in the rooms of the Royal Society of Medicine on April 29th and 30th and May 1st, under the presidency of Mr. **J. B. STORY**, F.R.C.S.I., whose opening address was reported in THE LANCET of May 15th, p. 1068.

Mr. **JOHN ROWAN** then opened a discussion on the

Non-operative Treatment of Glaucoma,

beginning with the question "Are not some cases of glaucoma better treated without operation, and, if so, what are the indications?" He had had a number of patients one eye of whom had been operated on, the other not. The operations had consisted in both iridectomy and trephining, by various good operators. Several patients had been kept under eserin for months, one for two years, with no deterioration in the eye condition, sometimes with improvement. A typical case he quoted was one with irregular contraction of the fields, plus tension, glaucomatous cupping, pale optic disc, with some atrophic appearance. Eserin was applied and continued, and the condition had remained as when first seen. Operation should be carried out when signs of advance of the disease were evident. In most cases of glaucoma he advised operation, and especially early operation. If he was right in contending that some cases were better without operation, he asked views as to the best indications for this.

Sir **ANDERSON CRITCHETT** agreed that the indication was to operate early, but all who had had experience must acknowledge, with pain and distress, that sometimes, whatever the type of operation carried out, there was a discouraging declension of vision. Some surgeons, indeed, had given up operating for chronic glaucoma.

Mr. **T. HARRISON BUTLER** said his habit was to operate on chronic glaucoma when the tonometer showed that the eye tension was raised and there were signs of functional failure. In these conditions he did not hesitate to operate even when it was the patient's only eye—indeed, the need for it seemed then increased. In some cases the vision after trephining was as good as 6/9. In one or two cases the lens had come forward.

Dr. **G. MACKAY** had noticed that when eserin or other miotic was used over long periods there was a tendency to the formation of pigmentary adhesions between iris and pupil, resulting in diminished transparency of the pupillary area. When examining cases of glaucoma the surgeon should be armed with a tonometer and a blood-pressure recorder. If the blood pressure were high, depletion by venesection should be a precedent to operation; then one class of cases in which there was hesitation about operating would be eliminated.

Mr. **RAYNER D. BATTEN** said that when the eye tension was about plus 1 and the cupping of the disc was in excess of the tension, this could usually be relieved by eserin and general constitutional treatment. In these cases he regarded the cupping of the disc as the disease, the glaucoma as the symptom. And the cupping was progressive, whether the tension was relieved or not. In some cases the cupping would increase the eye tension by interfering with posterior filtration.

Mr. **RICHARDSON CROSS** said that many cases of glaucoma called for operation without delay; in others caution should be exercised about interference. Even a good operation might reduce vision considerably. If central vision was good and there was no great narrowing of the fields, especially towards the fixation point, with an absence of inflammatory symptoms, one could safely rely on miotics. Alteration in the position and course of the vessels he regarded as a grave sign.

Mr. **TREACHER COLLINS** agreed that many cases of chronic glaucoma could be kept in check by the continuous use of eserin. He gave such patients eserin at first, and inspected the condition at frequent intervals. If the symptoms increased in spite of eserin, he advised operation. But additional factors which ought to be considered were the condition of the patient and his age—i.e., his expectation of life; his blood pressure must be taken into account too, for if it were high it was an additional danger in operating. But there was a most disappointing type of case, in which there ensued progressive failure of vision following a good operation.

Mr. **GRAY CLEGG** spoke of cases in which a halo was complained of, and in which the regular use of eserin kept serious developments at bay for a considerable time. But his patients were instructed to come at the least sign of subjective symptoms.

Mr. **R. R. CRUISE** thought the number of cases in which pressure had been overcome by drops must be small compared with those in which the results had been deplorable. He did not think the extraordinary value of the tonometer was at all sufficiently recognised; by its aid the exact progress of a case could be judged in the important matter of the ocular tension, which was the first indication that a case was going wrong.

Dr. **A. HUGH THOMPSON** said that as the ocular tension must vary from time to time, even at different hours in the same day, alteration in the visual fields would be a surer guide to the condition of a case of glaucoma than changes in tension. He had notes of hospital cases in which one eye of a patient had been operated upon, and its fellow had been kept under eserin for more than ten years, with very good results.

Mr. **BISHOP HARMAN** thought that the judgment concerning a case should be based upon the average rate of change going on. He quoted cases in which the regular use of eserin was successful over long periods.

Mr. **A. GREENE** thought it was to the physician one might turn for an explanation and remedy of the cause of glaucoma.

Mr. **BERNARD CRIDLAND** thought that most surgeons were not in favour of simple iridectomy for chronic glaucoma, especially in cases in which the field of vision had contracted and involved the fixation point. Von Graefe had pointed out that simple iridectomy in such a case was inhibitory on the nerve, and the vision rapidly got worse. Operation should be understood to mean decompression. In several cases he had obtained satisfactory fistulisation without touching the iris. He regarded the tonometer as giving the most valuable indication as to the progress of a case of glaucoma.

The **PRESIDENT** said that in cases in which the tension was distinctly high and there was contraction of the field and a central scotoma, he advised operation. The one he had done almost exclusively in recent years was trephining.

Infection after Cataract Operations.

Mr. **HARRISON BUTLER** discussed the probable reasons for the proportion of failures which occurred after cataract operations. There were two types of inflammation, having a different ætiology. The first type, the acute wound infection, the septic hyalitis, panophthalmitis, was most probably due to an infection from without, mostly by the pneumococcus, often derived from a diseased sac or an ethmoiditis. In the second group he thought the cause was mostly an endogenous infection or was due to toxæmia. He supported his views by quoting details of a number of cases. Diabetes he believed to be a fruitful cause of failure. He proceeded to give his experience with juvenile cataracts, uttering the warning that in children who seemed to be in poor condition operation should be deferred until they were strong, and care should be taken not to overlook any septic focus.

Mr. M. S. Mayou said that endogenous infection occurred, but in some cases organisms lay latent in the eye until a temporary lowering of the resistance revived their activity, and suppuration resulted.

Mr. Cruise did not think the services of the bacteriologist were enlisted so often as they should be in these cases. He spoke of cases in which the intestine or urine was contaminated, and an autogenous vaccine proved beneficial.

Diabetes in Relation to Eye Diseases.

On Friday morning Sir Archibald Garrod and Mr. R. Foster Moore opened a discussion on this subject.

Sir Archibald Garrod said the ocular troubles of diabetics were much less obvious to the physician than to the ophthalmic surgeon. He addressed himself chiefly to the subject of diabetic retinitis. In the diabetic form the ocular hæmorrhages were apt to be guttate rather than flame-shaped, the white spots more opaque and sharply circumscribed, more scattered, and less apt to group themselves around the macula. But albuminuria in diabetes did not necessarily point to serious renal damage; the amount of albumin in the renal cases gave no sure clue to the gravity of the kidney lesion. Diabetic retinitis was not to be expected in patients below middle age, but albuminuric retinitis was met with in young patients, even in children. This suggested that the occurrence of retinitis in diabetes was not to be attributed to the accumulation of sugar in the blood nor of the accompanying acetone bodies. A contributory cause must be looked for other than the disorder of carbohydrate and protein metabolism, and if it should be true that the retinitis was associated with cardio-vascular changes this suggested an explanation. Most of the patients in his wards who had developed retinitis with diabetes had shown evidences of renal disease also. He suggested that both diabetic and albuminuric retinitis had high blood pressure and associated arterial changes. More could now be learned from an estimation of the sugar in the blood than from that in the urine. A line should be drawn between acute diabetic cases of early life, which ran a rapidly fatal course, and the mild diabetes of middle or later life, which might persist for many years without grave detriment to health. He considered that the factor determining this was the age of the patients and the tissue changes of advancing years. Account must be taken of the character of the diabetes, as well as the ocular lesions seen. It was generally agreed that diabetic retinitis had not so grave a prognostic import as had the albuminuric. Cataract seemed to be the commonest eye trouble to which diabetics were especially liable. He concluded by a reference to the recent great advances in the treatment of diabetes, remarking that before operating on diabetic patients, ophthalmic surgeons should see that they underwent, for at least a fortnight, treatment by one of the hunger-day methods.

Mr. Foster Moore based his exposition on observations in 62 cases. The chief ocular complications of diabetes were retinitis, cataract, retro-bulbar neuritis, retinal and vitreous hæmorrhages, lipæmia retinalis. Lesser conditions met with included alterations in intraocular tension, alterations of refraction, iritis, debility of accommodation. Retinitis had affected his older patients only; there was only one as young as 39. These subjects usually had arterio-sclerosis also, sugar and albumin in the urine being common in them too. Of 51 cases of diabetes of all ages at St. Bartholomew's Hospital, only 5 had retinitis. Diabetics tended to develop hæmorrhages into the retina or vitreous. The prognosis of retinitis in diabetes was much less grave than in renal retinitis; 60 per cent. of Nettleship's cases lived longer than two years. The term "diabetic cataract" should be restricted to the somewhat rapid opacity of lens seen in young diabetic subjects. It was always bilateral and of a diffuse homogeneous type. Without having objective disease of any part of the eye, a certain number of diabetics developed defective vision. In some this was due to retro-bulbar neuritis. Six of his 62 patients had this. In certain cases of lipæmia a very characteristic ophthalmoscopic picture was seen. Concerning alterations of refraction, observers had noted a variation with the amount of sugar excreted; in most cases a decrease in the sugar output lessened the myopia. He had once seen an acute primary iritis develop in a patient who had diabetes, and in whom no other discoverable cause was present.

Dr. O. Leyton said that in diabetes mellitus the excretion of other substances than sugar was impaired. He had tested the excretory function in a large number of diabetics, and concluded that in most the kidney itself was somewhat changed. Because the blood pressure of a diabetic was not raised, it must not be concluded that the vessels were not changed profoundly. The retinitis he regarded as due to a toxin. He emphasised the great alteration in metabolism produced by alimentary rest.

Dr. Mackay said he had seen cataract develop to ripeness in so short a time as a week. He did not recall any special difficulty in the surgical treatment of cataract in glycosuric patients.

Mr. H. P. Adams said that of the last 31 cases of diabetic retinitis he had seen at the hospital, 22 were in women, 9 in men. Of 159 cases of other vascular troubles in the retina, 96 occurred in women, 63 in men. Of the 31 cases, 13 were 50 to 60 years of age at the onset, 15 between 60 and 70, 3 between 70 and 80. All but 5 of the 21 cases he had been able to trace were now dead. In those who lived longest after the disease was established the duration varied between eight and a half and four years.

Dr. P. J. Cammidge said that records of 350 cases of diabetes which he had seen during the past few years confirmed the conclusions as to the age-incidence of cataract and retinitis, and he thought this could only be explained by the chemical changes taking place in the body at the various ages. Glycosuria was not a disease; he had seen a number of young people who had persistent glycosuria which was very little affected by changes in diet and whose health did not suffer. Two main groups of diabetes were the *pancreatic* and the hepatic. In the latter there was an increased formation of amino-acids, of which tyrosin was one, and there was an increase of fat in the blood, and as the patient got worse this fat-content increased. He considered that diabetic cataract was associated with changes in the amino-acid and fat-content of the blood.

Dr. C. O. Hawthorne spoke of the association of ocular palsies with glycosuria and the fundus changes which occur when sugar is present in the urine. In diabetes mellitus the ocular palsy was probably a peripheral neuritis affecting the terminations of one or other ocular nerve. The cases in which retinitis was present were by no means always those in which glucose was extreme in amount. There were cases in which the discovery of retinitis was accidental; there was no complaint of sight, and it showed the importance of a routine ophthalmoscopic examination.

Mr. R. R. James gave his experience of extraction of cataracts in five young diabetics, with four satisfactory results. The ages of the patients ranged from 22 to 37 years. Cases of the kind were treated by the physicians in the hospital until there was a marked fall in the sugar output. He preferred not to do an iridectomy if it could be avoided.

Mr. P. C. Bardsley spoke of improvement in diabetics by the Allen Graham treatment, and the subsequent clearing up of the retinitis. In the so-called arteriosclerotic retinitis he did not doubt the cause was a toxin.

Mr. E. H. E. Stack spoke of the profound effect produced on a diabetic patient on first coming into hospital by the sudden change in conditions and surroundings, which sometimes brought on rapid coma. Since he had made the change very gradual, there had been a marked diminution of cases of coma.

Mr. J. Burdon-Cooper referred to the finding of tyrosin and cholesterin in the lenses which had been removed from diabetics; he had not tested them for glycogen. His impression was that the acids and ferments which were secreted by the ciliary body were responsible for the hydrolytic change in the lens.

Mr. Gray Clegg summarised his experiences in 1660 cases.

The Preventive Treatment of Ophthalmia Neonatorum.

Members paid a visit on Saturday morning to the Metropolitan Asylums Board special hospital for ophthalmia, Kentish Town, under the guidance of Mr. Mayou.

Dr. Gibbon Fitzgibbon (Master of the Rotunda Hospital, Dublin) opened the debate. From 1898 to 1919 (except for a short interval) there were 92 cases of ophthalmia neonatorum reported as having developed in the maternity department of the lying-in hospital. In that period 38,106 infants were born and left the hospital alive, giving an incidence-rate of 0·24 per cent. Credé's prophylactic method had been in use during this term. The routine at his hospital was, that as soon as the child was born the eyes were wiped clear of all mucus with swabs of boric lotion, without attempting to open the eyes. When the child had been bathed, one or two drops of a 1 per cent. solution of silver nitrate were dropped into each eye. No further treatment was adopted unless active disease appeared. He thought infants acquired the disease by passing through an infected canal. Purulent ophthalmia, he believed, developed after birth from infection of the conjunctiva by a variety of organisms, but the cases due to the gonococcus were the serious ones, and were most resistant to treatment. Many required no more than one application of silver nitrate, which was very efficacious. The pus should be wiped away before applying the remedy, otherwise the latter was liable to be partly decomposed by the pus. An efficient vaccine was a great help; 3 to 5 millions was the maximum dose for an infant.

Mr. Mayou had often found the Meibomian secretion to contain the xerosis bacillus on the third day of life. The greasy condition of the lid margin probably helped to prevent the infected vaginal discharge entering the conjunctival sac, but a more important factor was the quick passage of the child through the vagina. In one case of twins the first child was infected, the second escaped. He uttered a strong warning against the use of nitrate of silver by the inexperienced; 10 per cent. protargol was safer for those not conversant with the work. Local immunity was, he considered, closely bound up with the monocellular exudation occurring after the acute stage of the inflammation began to subside. St. Margaret's Hospital was opened by the Metropolitan Asylums Board in 1918, with 48 beds for women and infants, and there was need for extension. During 1919 146 mothers and 281 babies were admitted. There were eight wards, a theatre for treatment, and a small bacteriological laboratory. It was very necessary to have separate lavatory accommodation for the gonococcal and non-gonococcal cases. Much nursing was required; there was one nurse to every two patients here. Fly-nets to cover the cots were necessary in the summer. Despite notification, there was difficulty in getting patients sufficiently early; too large a proportion already had corneal ulcer when admitted. Silver preparations were not used until the swelling of the lids began to subside; used earlier they aggravated the condition. All preparations were rubbed in with wool mops, not merely laid on. External canthotomy he considered a valuable asset in treatment. Gonococci had been found in the conjunctiva 28 days after the cessation of all discharge. Mothers were instructed to return on the slightest sign of recurrence. Of 382 babies admitted 372 were suffering from ophthalmia neonatorum; of the latter 12 had only one eye affected. Of the 732 eyes 85 had the cornea ulcerated on admission. In 368 it was hazy. Of the 85 ulcerated eyes 28 had already perforated, and 33 perforated after admission; 28 did so on admission.

Dr. Mary Scharlieb had seen a good deal of ophthalmia neonatorum in India. She did not see it in her own practice because she followed out the instructions given at the large Vienna clinic where she was trained. The custom there was to wash the child's face as soon as the head was born, and the same with the hands and arms. As soon as the child's first toilet was finished, the eyes were carefully opened with two fingers, and nitrate of silver solution instilled into them. At that institution the occurrence of ophthalmia neonatorum was a rarity. She emphasised the importance of instructing medical students, midwives, and nurses to look out for trouble; thousands of eyes were lost because heed was not paid to the initial symptoms.

Dr. Elizabeth Macrory spoke of the rules of the Central Midwives Board in regard to the calling in of a medical man when anything unusual was noticed about an infant's eyes, and the notification of having done so. Many such infants were found not to have the disease. The incidence-rate of the condition per 1000 births in London varied between 10·37 in 1919 and 7·25 in 1915. In the practice of midwives the incidence per 1000 was 6·5 in 1916, 6·5 in 1917, 10·75 in 1918, 11·0 in 1919. The later increase might be due to greater care in notification. In 1914, out of 557 cases of inflammation of the eyes in the practice of midwives, 6 showed damage to the cornea; in 1919 out of 840 births in midwives' practice, 15 had corneal damage.

Mr. Sydney Stephenson said more than a hundred years had passed since Benjamin Gibson, of Manchester, laid down the rules whereby ophthalmia might be prevented in babies, and these could scarcely be improved upon at the present day. Credé's method of prophylaxis was the greatest step. In a series of 24,724 births up to 1895 in which Credé's method was carried out, ophthalmia occurred in only 0·65 per cent. He had collected the statistics from 1895, numbering 51,728 births, and giving an incidence-rate of only 0·75 per cent. When mother and child occupied the same bed infection might occur from the lochia. Not every case of ophthalmia was due to the gonococcus. He suggested that nitrate of silver solution of 1 per cent. strength should be used, as it was found to be as effective a protective as the 2 per cent. solution. He reminded the meeting of the simple cleansing of the eyelids at birth practised by Samuel Haig, of Camberwell, in 1879, with the result that he never had a case of ophthalmia neonatorum in his practice.

Dr. Maitland Ramsay gave his experiences of the disease in Glasgow. To achieve success parents must coöperate, but in many instances this was out of the question, owing to the ill-health, carelessness, or ignorance of the mother. Many of the children were kept under observation by the public health authorities until they attained school age. Arthritis, synovitis, glandular enlargement, &c., in the parents of the cases had been uncommon. When ophthalmia neonatorum was associated with syphilis, disastrous results were the rule. They coexisted in about 9 per cent. of the cases treated in the wards. In ordinary cases 6·9 cases were notified by doctors per 1000 births. In 3·5 per cent. of cases the signs were present within 12 hours of birth, in 56 per cent. in from one to four days, in 32 per cent. from the fourth to the eighth day. In 42 per cent. the gonococcus was found. The results of treatment would be better if compulsory removal to hospital could be carried out in every case in which the home surroundings were unsatisfactory.

Dr. J. Wharton briefly summarised the results obtained in Manchester. In 224 cases one or both eyes were lost beyond hope; in 229 cases an ulcer of the cornea had perforated, and he feared that most of these patients would be permanently blind. Since 1897 a special department for the treatment of cases as in-patients had been in operation at the Manchester Royal Eye Hospital, accommodation being provided for both mothers and infants.

Mr. A. L. Whitehead said that in Leeds last year there were 7837 births, of which 4433 were attended by midwives. The total notified cases of ophthalmia neonatorum numbered 105, half of them in midwife-attended cases. In the treatment hourly irrigation was carried out by nurses wearing rubber gloves, the solutions used being boric lotion or potassium permanganate, or 1 in 1000 biniodide of mercury. That was followed by drops of 20 per cent. argyrol every hour. If the cornea could not be well seen, external canthotomy was at once peformed.

Dr. Thomas Stevenson related briefly the routine treatment carried out at St. Paul's Eye Hospital, Liverpool, which was started in 1908.

Dr. C. Killick spoke of the work in Bradford.

Mr. J. B. Lawford criticised the recent omission from the Regulations of the Central Midwives Board of all reference to Credé's method, or any substitute for it.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH.

Treatment of Tuberculosis.

AT a meeting of this society held on May 5th, a discussion took place on the Treatment of Tuberculosis. The discussion was opened by Sir **ROBERT PHILIP**, who read a paper on the Modern Outlook on the Treatment of Tuberculosis, and by Sir **HENRY GAUVAIN**, who dealt with the Management of Non-Pulmonary Tuberculosis.

Sir Robert Philip contrasted the Hippocratic conception of phthisis with the modern outlook on tuberculosis, and showed how the disease, formerly regarded as always fatal, was one which satisfactorily yielded to treatment, particularly in the early stages. The widespread occurrence of tuberculosis and its natural tendency to cure had been demonstrated by many observers. Amongst the most striking figures were those of Reinhardt of Berne, who, in an extensive series of post-mortem examinations, made on individuals who had died from all varieties of disease, found evidences of tuberculosis in 96 per cent. of cases—32 per cent. showing active and 64 per cent. healed tubercle. It was well recognised that nature cured cases of the disease every day. The essentials of the development of tuberculosis were infection by the tubercle bacillus, the reaction of the tissues to invasion, and later the occurrence of systemic intoxication. The seat of the immediate localisation of the tubercular process was relatively unimportant. There was considerable resemblance between infection with tubercle and infection with syphilis, but tubercle was much more difficult to diagnose with certainty in the early stages. Its incubation period was prolonged and ill-defined; the possibilities of infection were numerous, obscure, and often connected with environment. After local infection with tubercle a sore might develop at the seat of inoculation, and in the guinea-pig after experimental injection with tuberculous material the occurrence of a sore was characteristic. The tubercle bacillus might enter the body by many different channels. The tonsils and posterior nares were important points of entry, and spread was by the lymphatics. A very acute form of lymphatic tuberculosis affected the Senegalese troops in France, and was accompanied by a high mortality. After entry of the bacillus, it might be conveyed to any part of the body, and the local lesion must be regarded as more or less incidental. The ultimate danger was the occurrence of systemic intoxication, which showed its effects most markedly upon the neuro-muscular structures, and which manifested itself early before the development of local physical signs. Cases should be frequently re-surveyed because of the possibility of recurrent manifestations, as even after apparent cure these cannot be excluded with certainty. Tuberculosis was a slow process as a rule, and a long period was required for efficient treatment. The official three months given under the National Health Insurance Act was useless, and was a waste of time and money. There was ample proof that proper treatment was followed by good results. Thirty years ago it was common to see advanced cases of pulmonary tuberculosis for the first time, whereas it was now rare. The progress that had been made was shown by the falling death-rate. In the 30 years from 1870 to 1900 the percentage fall in mortality was 41, and in the succeeding 20 years it was 45. The age of death was also considerably later. There was need for continuous investigation and fuller training of men on modern lines.

Sir **HENRY GAUVAIN** said that the treatment of non-pulmonary tuberculosis had largely been neglected owing to lack of opportunity. The average period of treatment usually accorded to such cases in hospital was one month, whereas it was recognised that cases of pulmonary tuberculosis required about two years. Surgical tuberculosis should no longer be considered as a local condition only. The "soil" was very important, and very largely influenced dissemination of the disease. Conservative treatment—by which was meant the adoption of all measures capable of increasing resistance—should be practised in preference to radical treatment, which was designed to remove the local manifestations. Conservative treatment meant suitable climate, fresh air, personal hygiene, and proper diet. While undergoing treatment proper occupation was necessary, and this should be of a kind to suit the particular class of case. A certain amount of discipline was also a necessity. Cases of surgical tuberculosis could be divided into three classes—those which required absolute rest in the recumbent posture, subacute or chronic cases which needed immobilisation of the affected part to allow of repair and to prevent deformity, and a class where support only was required. Heliotherapy was of value in some cases, which showed reaction to it by pigmentation. Excessive reaction must be avoided, and the patient should gradually be acclimatised to the treatment. Surgical treatment might be necessary for special complications such as tuberculous abscess or sinuses. Spontaneous opening of abscesses should never be allowed, as sinus formation was sure to follow. Instead of incision the part should be immobilised, and the abscess aspirated. By so doing, use was made of nature's barrier in the form of muscular aponeuroses and fasciæ. The good results following treatment along conservative lines were strikingly demonstrated by figures from the special hospital at Alton.

Mr. **JOHN FRASER** agreed with the efficacy of conservative methods in the treatment of surgical tuberculosis. He advocated, however, in addition, early operation in certain classes of cases, especially in early tubercle affecting the cervical glands, and where there was a focus of disease in a bone near a joint. In infants also, early operation might be desirable in some cases where it would be undesirable in older children. Extremely bad social conditions might also make operative interference more necessary.

Professor **G. L. GULLAND** emphasised the importance of goodwill on the part of the patient in making treatment a success.

Dr. **I. STRUTHERS STEWART** dealt with certain aspects of sanatorium treatment which were at present unsatisfactory, and urged the necessity for development and coördination of research.

Sir **DAVID WALLACE** referred particularly to tuberculosis of the genito-urinary tract.

Dr. **LOGAN TURNER** spoke of the frequency of laryngeal tuberculosis and of its influence on the prognosis in cases of phthisis, showing that the mortality was very appreciably increased.

Dr. **FERGUS HEWAT** referred to irritable heart as an important systemic manifestation in certain cases, and also of the necessity for repeated examination of the sputum.

Dr. **GEORGE MACKAY** and Dr. **W. G. SYM** dealt with tuberculous infections of the eye.—Professor **F. M. CAIRD**, Mr. **C. W. CATHCART**, and Dr. **CHALMERS WATSON** also spoke.

MANCHESTER MEDICAL SOCIETY.

Psychotherapy.

A MEETING of this society was held on March 3rd, Professor **R. B. WILD**, the President, being in the chair.

A discussion was introduced by Professor **T. H. PEAR** in a paper on Psychological Analysis.

By psychological analysis, he said, is meant here "any method whereby the nature and relationship of the causes responsible for the patient's (mental) condition are determined, and the condition removed by the rearrangement and readjustment of these causes."[1] The term is wider than psycho-analysis; the latter should be reserved to describe that method which owes its inception to Sigmund Freud. The present discussion attempted to describe the nature and uses of psychological analysis (of which psycho-analysis is one example) in the diagnosis and treatment of what are known as the "functional nervous disorders." Of these disabilities there are two kinds, often, but not always, sharply distinguished from each other: (*a*) conversion hysteria; (*b*) the anxiety neuroses. These two types of disorder may be symptomatic of different kinds of mentality in a patient, and the cure may necessitate different methods of treatment. The thesis here put forward is that though psychological analysis is only one method in psychotherapy; it is (*a*) sometimes the only method which will be ultimately successful; because it is (*b*) the only "radical" method.

The different psychological processes involved in the methods known as suggestion, persuasion, and analysis were then discussed and compared. Reference was made to the view taken of the differences between these disorders by Dr. Bernard Hart. It was pointed out that the meaning attached to the word "suggestion" is usually extremely vague, and that though probably suggestion enters into treatment both by persuasion and analysis, it can be theoretically distinguished from them. The definitions of suggestion and persuasion, given in the article quoted above, were further discussed. In conclusion, it was pointed out that the adoption of all methods of psychotherapy, and in particular of the analytic method, assumed a knowledge of the technique and of the psychological processes underlying them. Emphasis was laid upon the necessity of training medical students in the future to understand and to discriminate between the uses of these various methods.

The following took part in the discussion: Professor **E. S. REYNOLDS**, Dr. **D. E. CORE**, Dr. **S. HERBERT**, Dr. **A. V. STOCKS**, Dr. **S. R. WILSON**.

Reviews and Notices of Books.

THE PRINCIPLES OF ANATOMY AS SEEN IN THE HAND

By FREDERIC WOOD JONES, D.Sc , M.B., B S. Lond. London; J. and A. Churchill With 2 plates and 123 text figures. 1920. Pp 325. 15s.

ONE of the side results of the war is to be seen in the rediscovery of anatomy for clinical purposes, and it has been recognised by all who have had to do with the needs of the clinician that there are still uncharted and practically unknown details of bodily structure which, when worked out, will be made of value by the bedside This book does not, it may be, open up any of this unexplored territory, but the author employs paths rather out of the way, tracks little used by the crowd, to give the medical reader, and even the routine anatomist, glimpses of the interest lying round them in the sphere of their everyday work. One cannot help regretting that books of this kind—and there are too few of them—do not often find their way into the hands of the ordinary student. The present divorce of anatomical study from its clinical application deprives the average student of what would prove to be a powerful incentive to work, an exceptional teacher will meet the want by providing another interest, more strictly scientific and anatomical, and this volume on the hand should be a valuable adjunct to his efforts The time table of a school curriculum, however, does not leave much time for extraneous reading, and it is probable that the book, for that reason, will afford more pleasure to his teachers than to the student.

If it is true that descriptive human anatomy still presents opportunities for more research, the assertion is even more applicable to the subjects associated with it. The study of human development, for example, is a matter which, when we advance beyond the uninspiring and rather sterile products of German manufacture, will turn out to have much to suggest, not only in anatomical explanations, but in the comprehension of the genesis of many pathological states. Reading his book, one has perhaps the impression that Professor Wood Jones does not lay stress enough on the ontogenetic development of the human hand. For example, an argument perhaps as strong as any other in support of Humphry's views on the morphology of the skeleton of the thumb, which the author adopts, is to be found in the details of formation and attachment of the long flexor tendon of that digit, again, without wishing to disagree with the author's conclusions, it may be pointed out that some suggestion of a postminimus is ontogenetically afforded in the first attachments of the abductor of the little finger, if that muscle is considered to be a marginal member of a dorsal or inter metacarpal group. Similar criticism might be brought forward as argument against unreserved acceptance of some conclusions Professor Wood Jones believes that the hand is a primitive organ, more primitive in men, perhaps, than in some other animals, and he demonstrates his position by his formulæ and comparative observations, but the ontogenetic changes in the hand, even in the development of the apparently simple interossei, surely show that the human hand, so far, at least, as its intrinsic muscles are concerned, is a decided modification of what must have been a primitive condition. It would be a good thing to impress on the student the great value of the details of ontogenetic development

Turning to less contentious matters, it is no ordinary pleasure to one who cares for his subject and its history to come across the names of old time anatomists, extracts from whose half forgotten works are frequently put in with effect by the author Perhaps not the least interesting part of the work, from the student's point of view, will prove to be that which deals with the nervous connexions of the hand, in which many of the disconnected facts of his text books are put before him in ways both interesting and coherent. There are certain small errors that could be removed in a future issue. Thus Fig. 85 is not correct in some of its points, the term "intermediate" would be an improvement on "medial," which has other meanings in the vocabulary of many, and the superficial flexor of the digits is usually designated "sublimis." Professor Wood Jones has, in addition, an unaccountable tendency to give the name Humphray to the late well known Cambridge anatomist and surgeon. But these are very small matters, and it can be said at once, and heartily, that the book is one worth reading, and eminently readable, well got up, with clear and explanatory illustrations, and could with advantage be placed in the hands of every medical student who has attained to the investigation and contemplation of his intermediate subjects.

ROSE AND CARLESS'S MANUAL OF SURGERY.

Tenth edition By ALBERT CARLESS, C.B.E., M.B., M S. Lond , F.R C S. London. Baillière, Tindall, and Cox. 1920 Pp. 1562. 30s.

IN reviewing a new edition of a book so well known as "Rose and Carless's Manual of Surgery" it is unnecessary to notice more than the changes which have been made as compared with previous editions This is the tenth edition, and five years have elapsed since the last Five years of war and years in which the surgical skill of the medical profession was put to the severest tests. That the medical profession was not found wanting has been proclaimed publicly, never in the history of war has more been done for the wounded soldier. The fact that the medical profession was able to cope successfully with the thousands of severely wounded men was due to the sound training received during student life. There is no doubt that this text book has helped to give this training, and one would like Mr. Carless to feel that "the weary hours of study spent over its pages" were worth while.

The additions to the work are mainly in the direction of knowledge gained in the war, with regard to the treatment of infected wounds, of fractures, and in making good the defects following injuries. Another change is the gathering of the X ray pictures into a supplement at the end of the book, instead of dispersing them through the text This may be convenient for production, but of doubtful value to the student

CHAPITRES CHOISIS DE CHIRURGIE.

By G L REGARD. Paris A Maloine et Fils 1920 Pp 430 Fr.20

M. Regard, a civilian surgeon, served as Médecin Aide Major, and also as Chef d'Équipe Chirurgicale in the French Army. During four years of war he kept careful note of his observations which, together with the results of a considerable amount of experimental work, are now gathered together in the "Chapitres Choisis" The book does not pretend to be a text-book on war surgery, but it contains interesting chapters on many subjects, such as cranial lesions, shock, the treatment of wounds by auto vaccination, gas gangrene, fractures, and the repair of bone Though it does not contain any startling novelty, the work is interesting and unusual, owing to the inclusion in it of the results of experimental work, particularly with reference to shock and the regeneration of bone, which were designed to elucidate the clinical problems.

Though works on war surgery are not now urgently needed, this one is worth perusing, for, as M. Jacob says in the preface, it is "un beau livre."

JOURNALS.

Journal of Industrial Hygiene. London Macmillan and Co 3s 6d monthly, 21s per annum —The pages of this journal have contained in recent numbers articles referring to various branches of the wide field covered by the new science which is springing up relating to occupational preventive and curative medicine and surgery. Review of articles dealing with kindred subjects, although appearing in different numbers, will, we feel, be of more interest to our readers than reference to each issue of the journal. Three articles, for instance, appearing in the issues for February, March, and April may be dealt with in one group; they are contributed by Dr. T. M. Legge, and disclose the author's well known erudition His Lowell Institute lecture on the spirit of work in craft guilds throws an interesting light on the standard of honest work and good material maintained by mediæval craftsmen, and on the organisation which existed to ensure it; trade halls and trade pride then showed a spirit which is conspicuous by its absence from modern trade unionism.

> "Not until the workmen of to-day, in factory and workshop, again recapture this interest in their work, can we expect the same fine results from them. ...... The craftsman asked a good price for honest work made of sound material which would consequently last a long time. He did not try to dodge his neighbour and undersell him. The question of cheapness did not come in. Only occasionally do we read that the municipality had to interfere to regulate the price of goods because of extortion. A regular scale of charges was recognised and the skill of the craftsmen counted for what it was worth."

Dr. Legge passes from these general considerations to inquire how far industrial diseases occurred among the workers; he finds evidence of the existence of ill-health in the fact that "the craft guilds were the only friendly societies, benefit societies, and sick societies, that existed in their times." Nevertheless, although the hours of work which embraced the hours of daylight were long, work by night and on Sundays was forbidden. References in literature are few; Chaucer, it is true, represents the alchemist as suffering from plumbism.

> "And wher my colour was bothe fresh and reed,
> Now is it wan and of a leden hewe;
> Who-so it useth, sore shal he rewe.
> And of my swink yet blered is myn ye."

But the writer turns to Ramazzini for more direct evidence of diseases among craftsmen. This Italian savant at the end of the seventeenth century visited the workshops and saw there mercurial poisoning among goldsmiths, and lead poisoning among potters, painters, and artists; he also describes fibroid phthisis among stonemasons, potters, and miners of metallic ores. The writings of Ramazzini are becoming for industrial hygiene as classical as those of Hippocrates, wherein allusions may be found which can be made to fit nearly every modern instance, but being at times somewhat obscure as to their exact meaning. This famous physician appreciated the value of washing, and counselled all

> "that live by sordid slovenly trades, the frequent shifting of their linen and keeping their body clean; that by that means they may prevent, as far as it is possible, the diseases that flow from filth and nastiness."

And he anticipated more recent social thought with the words—

> "'Tis a sordid profit that is accompanied with the destruction of health."

Dr. Legge carries us forward nearly 150 years from this Italian physician to the English pioneer, Thackrah; he tells something of his life and work and something of the labour world as Thackrah knew it in the first half of last century. The influence of Thackrah upon the thought of his day is set forth; and we are told how he exposed the prevalence of woolsorters' disease and of high morbidity and mortality among those exposed to the inhalation of dust; and how—which marks an important epoch—he founded his deductions on statistical data. Thackrah had a sane judgment, was a keen observer and a clear writer; his work remains worthy of close attention to-day, and we thank Dr. Legge for reminding us of its importance and value.

Three other articles may be referred to together as they deal with aspects of industrial fatigue and unrest. Dr. S. Cobb, in the November number, discusses the psychological aspect and looks upon modern industrialism as "mentally insanitary." The worker has lost creative desire,

> "and the only reason left for labouring is the predatory desire to possess wealth—to get paid off and to do as little work as possible for as large a reward as possible."

Hence results a life of limited happiness and restricted personal development, a life directly conducive to industrial neuropsychosis—a term which may be held to apply to the "gradually accumulating fatigue of the over-driven industrial worker," but which also embraces repressed emotional cravings. Industrial conditions are the cause of industrial unrest, and the duty lies with industry to study and remedy the evil it has brought into existence. The social economist on the one side and the medical practitioner on the other must both be called in to aid, but neither will give of his best until both meet on the common ground of psychiatry.—R. A. Spaeth, in the January issue, following up his excellent exposition of the fatigue problem which appeared in the first number of the journal, deals more particularly with the prevention of industrial fatigue. He appreciates that until the working of the human machine is more accurately understood fatigue prevention cannot become an exact science; yet prevention is the object of the whole study. He says that there is no need to wait before starting on a fatigue-prevention campaign; a great variety of working conditions, often bizarre and unnatural, can be attacked forthwith. Illumination and ventilation are indeed becoming specialised branches of engineering; but other things are neglected, such as, for instance, the provision of seats, which requires careful study. Seats are needed for use during rest pauses, for use at processes usually done standing, and for sedentary occupations; in each case chairs of different type and construction are wanted, suited to the physique of each worker and to the character of the work. Spaeth advocates the introduction of rest pauses, especially at continuous repetitive processes after careful study of the effect produced; and in order to popularise them amongst piece-workers he even suggests payment for the resting time. This suggestion, we may remind our readers, was put forward in this country by the Health of Munition Workers Committee in their Interim Report when dealing with "Incentives to Work." Spaeth next points out that classification of processes and careful selection of workers according to their individual capacities would eliminate much unnecessary fatigue and labour turnover, and he suggests lines on which selection can be made. The value of Martin's spring balance as a physical test is pointed out, and of blood pressure and pulse-frequency as a physiological test, while the use of endurance and intelligence tests are also recommended. This writer looks with disfavour on "motion study" as practised in America.

> 'The aim of motion study and motion elimination has been primarily *output*—i.e., increased production. ...... Whether the fatigue at the end of the day or week is greater under the old or the new method is rarely asked."

The third article appears in the March number from the pens of F. B. and L. M. Gilbreth, who dwell upon the enormous loss to the community of unnecessary fatigue. First, there is the loss in production placed at an astounding figure.

> "There is also the loss in materials that are spoiled and in over-head charges caused by the unnecessarily fatigued worker. Again, there is loss due to absences caused by accident and sickness which are often the indirect results of unnecessary fatigue. Statistics show that the over-tired workers are the ones oftenest injured and oftenest absent. There is also the loss due to the lack of coöperation that comes as a result of the discontent due to over-fatigue, and the resentment due to a belief that the management has not done all it could to provide for the workers' relief from unnecessary fatigue."

The authors discuss the importance of illumination in lessening fatigue, and recommend the free use in factories of white paint on ceilings, on walls, on machinery, and throughout staircases. Plenty of light narrows the pupil of the eye and so increases the depth of focus of the eye; "the greater the depth of the focus, the less the muscles must adjust the convexity of the lens of the eye" during accommodation; thus eye-tiredness is saved. These authors also draw attention to the importance of studying seats; and claim that the average factory chair resembles a coffin, in that "the man who makes it does not require it, the man who buys it does not use it, and the man who uses it has little to say about it." The workers themselves even more than employers have to be educated in the matter of fatigue; educated to wear necessary spectacles, educated to recognise that high heels and pointed shoes are as much bad form in a factory as on the golf-links or tennis-court. Unnecessary fatigue to-day represents unnecessary waste at a time when the world cannot afford waste and requires increased production.

IN the *Bulletin de l'Académie de Médecine* for April 27th M. Arnold Netter returns to the subject of sleeping sickness, and quotes several instances to prove the theory of infection. He concludes his remarks with the following statements:—"Lethargic encephalitis is certainly contagious. The contagion is probably carried by the saliva. Because of the long persistence of the virus in the nervous centres the patient may be liable to give the infection during a long period. There are grave reasons for believing that encephalitis may be transmitted by a convalescent. There is reason for thinking that the malady may be contracted from a patient suffering from an arrested or incipient form or even from a healthy person who has been near a patient. These considerations, some proved and others probable, point to the fact that it is necessary to be cognisant of all established or merely suspected cases. Everyone in contact with these patients should be made aware of the possibility of direct or indirect infection. In the present state of things it would be difficult to enforce the isolation of patients for an indeterminate length of time where the greater number remain single cases without any precautions having been taken."—Two communications were made at the same meeting of the Académie by M. de Lapersonne and M. Achard on the Ocular Symptoms in Sleeping Sickness, and the whole subject was further discussed by Dr. Netter and Professor Widal.—The fourth communication of the meeting was made by Dr. Chauffard, who quoted many cases in proof of his contention that an attack of grippe makes the sufferer immune against further attacks during a certain period. Dr. Netter, in commenting on this communication, pointed out that while grippe influenza might confer immunity, this was not always the case with the many different forms of pseudo-grippe.—Dr. Bérard then read a paper on Operation for Goitre, in which he strongly advocated surgical treatment in such cases, especially before the setting in of complications, of which the most serious was thyroid cancer.

THE LANCET.

LONDON: SATURDAY, MAY 22, 1920.

The Joint Appeal for the Voluntary Hospitals.

We publish to-day an appeal signed by Queen ALEXANDRA, as President of the British Red Cross Society, and by the Duke of CONNAUGHT, as Grand Prior of the Order of St. John of Jerusalem, for the continuance in peace-time of the combined work of the Society and the Order—the Red Cross and the White. We may take it for granted that most of our readers have already seen the appeal, which has been circulated widely; but appended to the appeal there is an account of a survey which has been recently conducted by the two associations to ascertain the financial position and the volume of work done by certain of the voluntary civil hospitals, and a scheme for their monetary assistance and the increase of their activities. The outline of this scheme we were able to present to our readers last week, and now on page 1128 we publish it and the survey practically in full, for they provide the justification of the appeal. They show in brief, though with many details, the pecuniary position of the 550 provincial hospitals under consideration (the hospitals of the metropolis being considered to constitute a special case), the range of their efforts, and the difficulties under which they work, both those that are permanent and those that are aggravated by existing financial stress. In this way the reasons are supplied why the large sum of one million pounds per annum is wanted for the support and development of the institutions, and in what directions the money can be used most wisely. The survey and the scheme are the work of Sir NAPIER BURNETT, and form a valuable public and medical message. Much that is said in them has been said before, but in many directions the circumstances, though well known to medical men, will not be familiar to those who are asked to subscribe. If the documents are digested, donors will understand that their aid is being sought on business grounds, while medical men will be able to answer the now too common assertion that the voluntary hospital system is doomed.

For, as we have stated more than once in our columns lately, there has been in the public mind too great a feeling that the voluntary system has broken down. The numerous appeals in the public press have been supported by statements to this exact effect, and the individual needs of certain institutions have been taken to represent generally prevailing conditions. Hence the public has received an impression of helplessness—a feeling that it would serve no purpose to bolster up a system which was falling into decay. And this feeling has been particularly unfortunate because, at the very time when it was producing its greatest effect on the public, there were proceeding in two directions considered inquiries into all the facts from which it was believed by medical men the contrary view would emerge. Those who were aware of the part that was being played by the voluntary hospitals, and of the immense difficulties that would attend any wholesale suspension of their work in favour of a vast State-supported or rate-supported scheme, felt certain that both the survey of the Joint Council of the Red and White Crosses, and the Report, now imminent, from the Consultative Medical and Allied Council of the Ministry of Health would show that for the health work of the visible future the voluntary hospitals were absolutely essential. That their scope should be enlarged, their finances set in order, and their shares in a grand general plan allotted—these things were fully recognised, but the voluntary hospitals must remain, for the time being, the institutions around which and through which the further developments in the care of national health take place.

The Report of the Consultative Medical Council will appear in all probability next week, when the provincial health service outlined by Sir NAPIER BURNETT will be found to coincide in a valuable manner with the great and inclusive health scheme set up by the Council as the ideal towards which the Ministry of Health might well work. If the well-reasoned appeal of Queen ALEXANDRA and the Duke of CONNAUGHT, supported by Sir NAPIER BURNETT'S account of the survey of the provincial hospital should result in the finding of an annual income of a million to supplement the funds of the provincial hospitals, a practical step will have been taken to carry out the recommendations of the Medical Consultative Council. The hospital survey is only a first instalment, but it indicates in detail where help is urgently required, and we would draw special attention to two features which should appeal to all business men. Under the scheme it is suggested that there should be coöperative buying of hospital commodities, and the British Red Cross Society proposes to use its large storage accommodation in London, where necessary articles could be kept in bulk. This would mean both buying in bulk, and buying on analysis and on sample, and also in most advantageous markets. A second great point in the scheme is the recognition of the value of convalescent hospitals in two directions—early and late. The public and the medical profession know full well the value of the convalescent home, both as making space in hospitals for more acute cases and as giving to those who have passed from that acute stage a more reasonable chance of accelerated health; but the idea that convalescent homes should be established where early cases could be seen and prevented from swelling later the hospital population is, we believe, a new feature in hospital work.

◆

Left-handedness and Stammering.

In the *Times* Educational Supplement of May 6th some interesting experiments on children are described by Mr. A. E. LEWIS, headmaster of the Lingfield Colony Special Schools. These children had remained stationary for from two to four years and showed an average mental retardation (by the Binet Simon tests) of five or six years. They could not be taught to write, "they could not recognise letters by sound, and they had no idea of number or value." Mr. LEWIS proceeded to teach them to use the left hand in blackboard drawing—at first from the shoulder, and later, when definite progress had begun, from the elbow and wrist, with a smaller scale of movement. All the actions taught were mirror movements—i.e., the *reverse* of the usual right-hand movements. Besides the alphabet, they were trained in the visual memory of pictures and objects, and in their pictorial expression. By the end of the third month over half the class could connect sound with letter, the symbols, of course, being in mirror-writing. They now began to practise (*unreversed*, that is) right-hand movements with the left hand. But this soon resulted in the appearance of a pronounced stammer. The stammer only appeared when the left hand was made to perform movements in the same directions as those normally performed by the right. Left-handed work was therefore at once replaced by practice in ambidexterity. The blackboard was again employed for large-scale drawing from the shoulder, made by the two arms simultaneously, the left carrying out the mirrored movements of the right. The children were also trained in other bi-manual exercises, e.g., in throwing balls and in swinging light clubs. The great fault at first was a want of uniformity on the two sides, the left-sided movements being dominant, and the right subsidiary. Gradually, both hands began to acquire skill and steadiness, the speech defects disappeared, the Binet-Simon tests showed steady mental improvement, and the children could soon write simple letters and syllables from copy and dictation.

In considering the significance of Mr. Lewis's communication, certain other results must be borne in mind:—

(i.) At the British Psychological Society's meeting on May 12th, Mr. Hugh Gordon showed that the percentage of left-handed children is nearly three times as great among the mentally defective as among normal children.

(ii.) At least two previous investigators have independently found that stammering is commoner among left-handed children, when taught to become right-handed writers, than among other groups of children.

(iii.) From some as yet unpublished experiments of Miss Lucy Fildes, Cambridge Research Student to the Board of Control, it appears that children who have been pronounced "mind-blind" can be successfully taught their letters, provided that they are instructed appropriately; under such conditions they can relatively easily learn a strange (e.g., the Greek) alphabet.

(iv.) There is a transfer in the practice effects acquired on one side of the body to the other.

Mr. Lewis supposes that his results are dependent on the "opening up of additional centres in the brain." "Why," he asks, "should we not, by making the child left-sided, render possible the development of other centres on the right side of the brain as well" as those on the left side? But in the light of the additional facts just quoted other and far more likely explanations are possible. In the first place, since left-handedness is, according to Mr. Gordon, especially frequent (18 per cent.) among mental defectives, it is hardly surprising that education of the left hand, even though so long delayed, should in left-handed mentally retarded children have met with motor success. This factor, however, is of relatively slight importance compared with the following. Both in the right-handed and in the left-handed of such children, their backwardness of intellect had become considerably less pronounced than it was when they were first taught to use the right hand. Thanks to Mr. Lewis's enthusiasm, they were trained in left-handed movements by the most modern and improved methods placed in the hands of most expert and interested teachers, whereas their early training with the right hand had probably occurred in a normal school, and was foredoomed to failure. From Miss Fildes's already mentioned observations such early failure appears, in the case of mentally defective children, to be an effective barrier to later progress. It is only when special methods are subsequently employed in the right way that interest can again be awakened and that the enormously powerful suggestions, once acquired, of incompetence and certain failure can be frustrated. Even then the ill-effects may perhaps be perpetuated, as in Mr. Lewis's children, by far slower improvement on the side affected.

Further, the stammering on attempting to reverse previously acquired movements of the left hand appears to be related to that already known to tend to occur when in the left-handed the right hand is trained, in reversed movements, to replace the left. The latter case is not difficult to explain, as it involves a call on the cerebral hemisphere contralateral to that on which the speech centres are being predominantly developed, and so upsets the close anatomical association normally existing between hand and speech movement centres. But, according to Mr. Lewis's results, the learning of reversed movements on the *same* side as that on which the original movements were practised is apt, at all events in mentally defective children, to disturb the speech mechanism. If we can safely eliminate the effects of the previous futile training with the right hand, it would appear that the incoördination produced by learning to reverse acquired movement, whether ipsi- or contra-laterally, affects in some way not yet understood, the coördination of speech among the mentally defective. This is a matter clearly needing and readily capable of further investigation. Meanwhile we may conclude that Mr. Lewis's promising results are more easily explained by the psychological effects of enthusiasm, suggestion, and improved methods of training than by the mere "opening up of additional" motor cortical centres in the opposite hemisphere.

The Tuberculosis Rally.

Last week and next week include at least three important meetings of medical men and women specially interested in tuberculosis, its prevention, and its treatment. And it is well that this should be so, for a certain hopelessness is becoming apparent among the younger generation regarding the efficacy of our present efforts, in face of which it is no use simply to reiterate the claim that hygienic-dietetic treatment would have been a sovran remedy had it been carried out properly. Gallant persons, young enough to look coldly and without personal bias upon the results of hygiene and diet applied as curatives, are willing to concede their value as preventives. But when they are told, by those who think they know, that in sanatoriums greatly enlarged in size and number, with more prolonged treatment and more adequate after-treatment, is to be found the one and only solution of the tuberculosis problem, they are apt to show incredulity. Institutional treatment, ineffective in the spacious days before the war when the land flowed with milk and cod-liver oil, is likely to remain ineffective in the straits and subterfuges of an impoverished generation. The housing question suggests an analogy. In 1914 it seemed capable of solution on 1914 principles; nothing is clear in 1920 except the impracticability of such a solution.

Something of this was doubtless in the minds of the promoters of the Leeds Congress of the Tuberculosis Society on May 13th and 14th, for Dr. H. DE CARLE WOODCOCK, who presided, took as his theme the necessity for research and coördination in the eradication of tuberculosis, leading up to the resolution proposed by Professor BENJAMIN MOORE, that—

> "In the opinion of this Congress a conference should take place between those actively engaged in tuberculosis work and those engaged in research work, to arrange the lines on which future investigation should be conducted and the manner in which records should be kept and collated and the results circulated."

Were all the hundreds of municipal officers at present occupied with the clinical study of tuberculosis imbued—as many of them already are—with the spirit of research, and seized of the best lines on which it should be conducted, the tuberculosis problem would soon yield up some of its closely guarded and ramifying secrets. Investigations conducted for the Medical Research Council, such as those into the incidence of phthisis in relation to occupation, especially munition making, the mortality after sanatorium treatment and BROWNLEE's exhaustive search for a lead from epidemiological data, should form the basic knowledge of the tuberculosis service, and much more might be done to bring research and routine into fruitful partnership. Now that the Research Council *is set free from much of its urgent war work the* claims of the biggest peace time killer and maimer of human lives become very insistent.

Leisure of mind is necessary for research of whatever kind, and it is only a happy and satisfied mind which is leisurely. The assertion of its rightful position has been rather an absorbing task for the youthful tuberculosis service, but, now that the service has arrived, the tuberculosis officer, using the term in a wide sense, is free to develop many points of contact. The meeting, called for May 28th, at which Dr. F. N. KAY MENZIES will preside, is to form a tubercle group within the general society of health officers. The relation of tuberculosis to municipal hygiene and administration is obviously as close as that of measles or venereal control or infant welfare, and we assume that the general health officers, who now largely preponderate in the counsels of the Society of Medical Officers of Health, are prepared to welcome a fuller representation of special departments. The newly formed Society of Superintendents of Tuberculosis Institutions, which held its first general meeting on May 17th, devoted its attention at once to the big question of the ventilation and heating of tuberculosis institutions, the debate being opened by Dr. LEONARD HILL. There is, we have no doubt, enough interest in the subject of tuberculosis and in its votaries to justify several branches of active work. The central link which binds and coordinates is now and will increasingly be—Research.

MINISTRY OF HEALTH: NEW MEDICAL APPOINTMENTS.—In pursuance of the expressed decision of the Minister of Health to enlarge the scope of the medical side of the Ministry, especially in connexion with tuberculosis, general sanitation and epidemiology, venereal disease, international health work, infectious disease and the administrative work of port sanitary authorities, Dr. Addison has made the following additional appointments to the medical staff of the Ministry: Drs. James Fairley, J. Alison Glover, F. W. Higgs, A. A. Jubb, R. Bruce Low (junior), A. T. McWhirter, A. C. Parsons, G. Raffan, A. B. Smallman, P. G. Stock, F. L. Sturdee, E. N. White, D. J. Williamson, W. P. Yetts.

Annotations.

"Ne quid nimis."

THE INAUGURATION OF THE ASSOCIATION OF SURGEONS.

AT the Royal College of Surgeons of England last week Sir John Bland Sutton, as president of the newly inaugurated Association of Surgeons of Great Britain and Ireland, delivered an address in which, with erudition, humour, and biblical simplicity, he explained the need for the new organisation and the problems which it has before it. As our readers will remember, the Association originated with Sir Berkeley Moynihan, who suggested its formation to Sir Rickman Godlee in 1914. War intervened, but its cessation having allowed the suspended activities to be resumed, the Association has come into being, and its rules and programme have been laid down. The members, who are all engaged in the active practice of surgery or surgical research, will meet at stated intervals and at appropriate centres for private debate. The proceedings will later be reported in the *British Journal of Surgery*, which becomes the official organ of the Association, but the absence of reporters from the actual sessions will ensure that unfinished work will not be prematurely published and that the debates will not lose the value that is born of freedom of speech. Sir John Bland Sutton gave the movement a characteristic start by a dinner, which he gave on the evening of Thursday, May 13th, at Claridge's Hotel. The dinner was an act of private hospitality, most hospitably conceived; moreover, as falling under the proceedings of the new Association, it ought, we suppose, to escape publicity. But reference must be made to a short exposition by Sir Berkeley Moynihan of what might be expected from the Association if the spirit in which it had been born continued to infuse its proceedings. He pointed out that the motive for starting the Association, which had received great encouragement from Sir Rickman Godlee and his presidential successor at the Royal College of Surgeons of England, Sir George Makins, was to advance by concerted effort the science and art of surgery in a country where so much of the original work in surgery had been laid down. Surgery, said Sir Berkeley Moynihan, cannot well be a gregarious profession, but in England it is too much concerned with individual and local efforts. It is the intention of the Association to turn the deep currents into broader channels. He concluded that so far as material things—rules and membership—were concerned, the Association was now well fashioned, all that was required being that the ideals which had led to its institution should draw continued vitality from the enthusiasm of the members. We are confident that the new Association will be of the greatest value to progressive surgery.

A NATIONAL COLLECTION OF TYPE CULTURES.

IN our issue of May 15th we published a special article on the proposal of the Medical Research Council to establish a national collection of type cultures. The importance of the subject is worth insisting upon. A complete collection of authentic cultures of bacteria would undoubtedly be of immense value to scientific workers. It would be easy to show how seriously the progress of bacteriology has been handicapped by the absence of such a collection. Consider, for example, the amount of labour that was expended during the war in unravelling the history of Pasteur's *Vibrion septique* and Koch's *B. œdematis maligni*. In the end it was shown that the organisms were identical, but the absence of authentic cultures of the original organisms studied by Koch and Pasteur compelled bacteriologists interested in gas gangrene to expend a great deal of energy and time in settling a point which might have been easily solved under the conditions the Medical Research Council hopes to establish. Some months ago we pointed to the difficulties under which bacteriologists laboured during the war in diagnosing bacillary dysentery. Professor F. W. Andrewes and Dr. A. C. Inman have recently published an account of their work on the Flexner group of dysentery bacilli in which they have isolated five strains of *B. dysenteriæ* (Flexner). These strains, and consequently the corresponding agglutinating sera, were not available during war, though Kruse, in 1912, had isolated the organisms. Such stories of the failure of individualism in science could be told *ad nauseam*. We simply wish to urge that we have now reached the stage at which organised coöperation must come into play. It is, indeed, fortunate that the Medical Research Council has decided to organise this department of our common effort and put it on a sound footing. The Council has done well to secure the services of Dr. J. C. G. Ledingham and his colleagues. But we should like to add that the hearty coöperation of all bacteriologists is essential if we are to enjoy in the future the full advantages of the scheme.

MAN AND DISEASE.

THE tendency, already manifest before the war, to seek vitalistic instead of merely mechanistic interpretations of biological facts, and to insist on the importance of *Bildung* rather than of *Gestalt*, has lately become more marked. At the same time the scientific importance and educative value of the neo-Lamarckian conceptions have been more widely realised, and the relation to medicine of these and other subjects of inquiry, biological and philosophical, has received greater attention. Dr. F. G. Crookshank recently delivered, in the Pathological Theatre at Cambridge, three lectures entitled "Man and Disease," under the auspices of the Chadwick Trust, and took occasion to review some of these recent trends of thought to which we have made allusion, discussing their bearing on modern notions of disease and the resulting schemes for its prevention or alleviation.

In the first lecture of the series the origins of our conceptions of disease and diseases was sketched, and it was pointed out that two popular and professional schools of thought have always existed—the one, chiefly interested in external agencies, actual or suppositious, and now represented by those "realists" (in the scholastic sense) who regard diseases as attacking "entities," to be "stamped out"; and the other, more content with observing what is actually wrong with the sufferer (and how and why), and more inclined to throw the responsibility for ill-health upon those who, for themselves or their future offspring, neglect the personal effort necessary to secure due adjustment and to practise right living. Neither view has absolute value, but the popularity of the former is largely responsible for many alluring "campaigns" against this, that, or the other "disease"; and neglect of the latter tends to involve an increasing personal and racial helplessness.

In the second lecture a plea was entered for a return to the older "functional" and "synthetic" standpoint in respect of biology and that department of biology we call medicine, for materialistic and disintegrative methods of thought have failed to elucidate as completely as was once hoped the problems at issue. A vitalistic conception of disease was declared to be perfectly compatible with the teachings of Roux, the biologist, and Butler, the philosopher. Many converging lines of thought, indeed, appear to warrant us in considering the organic changes in disease as expressions of the disordered "inner" vegetative functions of cells, tissues, and organs rather than as imposed from without, or as Galenical "substances" lying behind the Galenical "shadow" of the symptoms.

In the concluding lecture the community was regarded as an organisation-complex, in the same manner as the "organism" is found to be a complex of lesser units, and they of others still simpler. Epidemiology is then concerned with disorders of health of collectivities and not of mere aggregations of individuals, and is inseparable *in its functions from sociology and the science of* government. Moreover, most forms of epidemic disease are definitely associated with social, economic, and allied conditions, while the greater pestilences may ultimately depend upon factors affecting all forms of animal and vegetable life upon the planet and provoking the harmful activity of the minuter parasites. The true basis of communal health, as of personal health, is to be found in the building up of the sense of responsibility of the "unit" concerned in each case, and in the exercise of effort and endeavour, in the interest of the still greater "complexes" of which each unit is a component; and in this connexion it is impossible to consider the health of mankind without reference to the prevention of international warfare—the greatest mundane cause of disordered health. In conclusion, it was pointed out how very clearly recent lines of thought tend to reinforce the wholesome, vigorous, and broad views and policies of Chadwick and his associates, who refused to entertain the narrower and particularist ideas so popular, in respect of "diseases," during the period now drawing to a close.

Sir Clifford Allbutt, who presided at the last, and Sir G. Sims Woodhead, who took the chair at the second lecture, both spoke of the advantages of taking a broad and comprehensive view of the nature of disease and the many factors involved in its production, as well as of the necessity for emphasising the importance of effort, and the sense of personal and communal responsibility in the prevention of disease.

EXTERMINATING YELLOW FEVER.

IN recent years there has been, without doubt, a considerable reduction in the amount of yellow fever occurring in the regions previously notorious for its ravages and known as endemic centres of the disease. This decrease in the incidence of yellow fever has been due in part to the application of the measures recommended by the American Commission which reported in 1900. One of the chief of these measures was the destruction of the stegomyia mosquito, the proven vector of the infection to man. Among the places which benefited as a result of this preventive action were Habana, Rio de Janeiro, and Panama, all well known at one time as active diffusing centres of yellow fever. Not only did these and other places directly benefit themselves by the anti-stegomyia measures, but they ceased to distribute the infection through shipping to other ports of South and Central America, and in this way caused a diminished incidence of the malady. The Yellow Fever Committee appointed by the Indian Government, to which attention was recently called in our Notes from India, suggests the desirability of keeping in personal touch with the endemic centres of disease elsewhere. It cannot be denied, however, that some other towns than the three named above, formerly endemic centres of yellow-fever, have also shown of late years a remarkable decrease, amounting in some instances to an entire disappearance of the disease, notwithstanding that no action at all had been taken to destroy stegomyiæ, and notwithstanding that these insects continued to multiply in enormous numbers. In such cases the decrease of the malady has been due to what is termed "spontaneous elimination." In the recently issued number of the *Annals of Tropical Medicine and Parasitology*, Vol. XIII., No. 4, Assistant Surgeon-General H. R. Carter, of the U.S. Public Health Service, discusses this subject and offers some explanation of the spontaneous elimination of yellow fever from its former endemic centres. Among the examples he mentions as having been freed from yellow fever are some of the smaller ports of Cuba, also La Guaira and Maracaibo in Venezuela, Cartagena in Columbia, and Corinto in Nicaragua, all of which in the past had an evil reputation as regards the disease. He points out that for the spread of yellow fever in a community three factors are needed—namely: (1) the presence of a person or persons in the early stages of a yellow fever attack—i.e., the carriers of the infection; (2) a sufficient number of active stegomyia, the vectors of the disease; and (3) the presence of susceptible persons. These three factors must be present together at the same time. The stegomyia gets infected by biting the carrier in the early days of his attack, and this mosquito after a time is able to convey yellow fever parasites to the susceptible person—the non-immune—whom it bites. The stegomyia remains infective during the rest of its short life, which Dr. Carter estimates will terminate at about ten days after its infection. If there are no immunes present to be bitten, and thus renew the stock of virus from which fresh stegomyiæ can become infected, the infection must die out. Susceptible persons are therefore necessary for the continuance of yellow fever in a community. Such people must not only be present, but must be present under certain conditions of time and place with relation to stegomyiæ infected from other persons with yellow fever. If in a community there are no susceptible persons fulfilling these conditions, yellow fever will disappear, and if, as Dr. Carter believes, one attack of this disease confers permanent immunity, such a community will have in time no people left susceptible to the malady, unless there is an introduction of non-immunes from without. Yellow fever, therefore, would in this way disappear, and as soon as the already infected mosquitoes died off the yellow fever parasites would disappear and the community would be free of the infection. An immigration of susceptible people, then, is necessary for the continuation of yellow fever in a community; if this immigration fails or fails to fulfil certain conditions the disease disappears. This Dr. Carter terms "the elimination of yellow fever by failure of the human host." The towns which have been freed from the malady in this way are generally small or of moderate size, out of the way of commerce, and receiving little immigration of susceptible persons. It has been noticed that other towns have suffered less and less from yellow fever as their prosperity declined and the arrivals of traders and others decreased. The decline of the sugar industry in some of the West Indian islands was followed by a great diminution of yellow fever. The withdrawal of European garrisons and fleets from the West Indies and Caribbean Sea led to a great decrease in the amount of yellow fever occurring in these regions. Even the Great War has helped by stopping European immigration to South and Central America; and the consequent commercial depression by causing lessened travel has also contributed towards this end by cutting off the supply of susceptible persons. Yellow fever, therefore, in recent years has been greatly reduced, first of all by the application of the scientific method of stegomyia destruction, especially in the larger towns, and secondly by "spontaneous elimination by failure of the human host" in the smaller and more remote endemic centres. There are, of course, other agencies under modern conditions also at work tending to diminish the spread of yellow fever. In conclusion, Dr. Carter believes that yellow fever may in time be exterminated altogether. Many of the higher forms of life, he says, have permanently disappeared from the earth, some of them even in our own times, and there is no reason why concerted attempts should not be made, perhaps, on an international basis, to exterminate a micro-organism such as that of yellow fever, which is pathogenic to man and which in the past has taken a heavy toll of human life. We hope that Dr. Carter's contentions will receive the attention of the International Health Bureau.

INTERNATIONAL PUBLIC HEALTH NURSING.

ORGANISED public health is the greatest immediate need of the Old World, and the organisers are constantly met with the difficulty of finding trained personnel. One of the first objectives of the League of Red Cross Societies has therefore been to seek out in all countries young women to be trained both in sick nursing and in public health work, to assist them in obtaining the necessary training, and to return them to their own countries as pioneers in public health work. Eventually the League advocates the establishment of a model training school or schools for public health nursing; but, pending this, it has been decided to make use of existing facilities, and King's College for Women, London, has been selected as the institution at which training will be given in public health nursing to the holders of the League's scholarships. The course of training will be conducted in the Household and Social Science Department of the College, beginning with the academic year 1920–21. Acting on the suggestion of Miss Alice Fitzgerald, chief of the League's Department of Nursing, and formerly of the Johns Hopkins Hospital, Baltimore, ten scholarships have been established, each of the value of $1000, to cover tuition and living expenses through the full college term of 10 months. Travelling expenses to and from London will be paid to the holders of the scholarships. Additional scholarships are to be established by National Red Cross Societies, and it is hoped that the first group of nurses to take the London training will number at least 20. The students will live in one of the residences attached to King's College under the supervision of Miss Gertrude Cowlin, assistant chief of the Department of

Nursing of the League of Red Cross Societies, and formerly organising secretary of the College of Nursing. The course of training will include physiology, bacteriology, household science, hygiene, and elementary social economics. The practical course will cover child welfare school clinics, tuberculosis, rural work, and district nursing. The students will also have the opportunity of visiting centres of social work. It is felt by the League that a year's contact with representatives of 20 other nations should help the pupils to a cosmopolitan outlook. After their return to their own countries, at the end of the course, the nurses will be expected to maintain communication with the League of Red Cross Societies, and a plan is under consideration for travelling field secretaries to assist them in becoming pioneers of public health nursing.

OPHTHALMOLOGY IN THE FINAL PASS EXAMINATION.

THE address of the president of the Ophthalmological Society, reported in our issue of May 15th, should go some way towards convincing the General Medical Council of the value of the reform for which he pleaded, namely, that ophthalmology should be included as a necessary part of the final pass examination and that the examination in this subject should be conducted by ophthalmic surgeons. To be effective it must include the clinical examination of cases both external and ophthalmoscopic. This does not mean that it is considered necessary for the general practitioner to have the detailed knowledge of the subject which is expected of the specialist, but rather that he should be able to recognise promptly such injuries and diseases of the eye as he is likely to meet with in general practice, and for which prompt treatment is essential, and in the second place, that he should be sufficiently at home with the ophthalmoscope to identify those conditions of the fundus which commonly constitute symptoms of general disease, some of these being essential to diagnosis. To the objection that such an examination would overload the curriculum, Mr. Story put forward his own experience as an examiner for over 30 years in Ireland, where the clinical examination that he advocates has been in force with excellent results. To the other objection that if an examination in ophthalmology is instituted other special branches of surgery will soon claim a similar privilege, he replied by pointing out that the importance of ocular signs and symptoms in serious constitutional diseases is much greater than can be assigned to any of the other organs usually taken up as specialties.

THE METABOLISM AND EXCRETION OF QUININE.

THE War Office has reprinted, in separate form, that portion of its recently-issued volume of "Observations on Malaria" which deals with the excretion of quinine. This subject is reported on by Dr. M. Nierenstein, lecturer on bio-chemistry in the University of Bristol, who was working during the war under Sir Ronald Ross at the malaria laboratory of the 4th London General Hospital. Dr. Nierenstein's first task was to compare the reliability of the various tests for quinine in urine. The most delicate of the qualitative methods is, he finds, that devised in 1853 by Herapath, of Bristol, and recently elaborated by Ramsden and Lipkin, of Liverpool. A number of quantitative methods was also tested critically, and that of Barratt and Yorke selected as being most reliable. Using this technique, Dr. Nierenstein made 1668 estimations of the excretion of quinine, and it is on this basis that he draws his conclusions. From these it appears that only about half the quinine administered to the human subject it excreted as such in the urine. The remainder, is seems, is metabolised, and two disintegration products, quitinine and hæmoquinic acid, were found in the urine. This latter was almost constantly present in the urine of blackwater fever cases, and in much larger quantities than in the urine of ordinary malarial patients. It was found that variation in the dosage from 20 to 70 gr. daily produced little or no variation in the proportion of quinine excreted unchanged, but that a dosage of over 30 gr. per diem, which raised the unchanged quinine in the urine above 11 gr. per litre, was apt to cause albuminuria. Variations in the preparations used and in the methods of administration made no great difference to the proportion excreted unchanged. Dr. Nierenstein's general statements are supported by a great wealth of detail in his report, which deserves close study.

PLEURAL EFFUSION WITH DEPRESSION OF THE DIAPHRAGM PRODUCING AN ABDOMINAL TUMOUR.

IN the *American Journal of the Medical Sciences* for March Dr. David Riesman has described a very rare result of pleural effusion—depression of the diaphragm producing an abdominal tumour. He first encountered this condition at a necropsy. On opening the abdomen he found in the left upper quadrant a large, smooth, tense tumour, which proved to be a bag made by the diaphragm turned inside out and filled with pleural fluid. Subsequently he has seen the condition twice, in both cases clinically.

In one case the patient, a widow, aged 77 years, came under observation in April, 1918. For years she had suffered from diabetes mellitus and chronic nephritis with moderate hypertension. There were diabetic cataract and retinal hæmorrhages. The heart was slightly enlarged, there was a soft systolic murmur, and the legs were somewhat œdematous. The urine contained sugar up to 3·2 per cent., and albumin from traces up to 2·8 g. per litre. The quantity was usually about 1500 c.cm. and the sp. gr. varied from 1007 to 1013. Unlike most cases of coexisting nephritis and diabetes, the sugar did not vary in inverse proportion to the albumin. Under treatment she improved. In June, 1919, she was seized with acute indigestion, characterised by abdominal pain radiating to the back, nausea, vomiting, and slight diarrhœa. Within a few days she began to suffer from dyspnœa. On examination the lips were somewhat cyanosed and the pulse rapid, but there was no fever. The upper left half of the abdomen was occupied by a tense rounded, slightly uneven, somewhat tender mass ; it extended forward to the mid-clavicular line and downwards to the level of the umbilicus. The left chest was visibly distended and enlarged. The percussion note was flat over the whole left chest. No heart sounds could be heard there ; the apex beat was just within the right nipple line in the fifth interspace. Bronchial breathing and bronchophony were heard over the left chest. Dr. Riesman concluded that the abdominal tumour was the inverted diaphragm containing pleural fluid ; this was confirmed by paracentesis. After slowly drawing off 5 pints of fluid, the tumour could no longer be felt. Fearing pulmonary œdema, Dr. Riesman remained with the patient. In the first half hour she was comfortable and greatly relieved. Then suddenly the lungs filled with fluid, loud bubbling râles could be heard everywhere, and the breathing became rattling and terribly laboured. A violent cough, which brought up little fluid, added to the distress. The face became purple, the skin cold and clammy, and death seemed imminent. A hypodermic injection of morphine and atropine had no effect. Dry cups were applied to the back and, as if by magic, every râle disappeared. After a proper interval the cups were removed and the œdema immediately returned, but it was slight and caused little distress. From that time improvement was rapid. When seen again in the latter part of July a considerable accumulation of fluid had taken place, but the abdominal tumour was smaller than before. Paracentesis was again performed, and the tumour vanished. She was in good condition at the time of the report.

In most of the text-books depression of the diaphragm as a result of pleural effusion is not mentioned. However, Wilson Fox, in his monumental work, says: "When the effusion is large the diaphragm may pass below the ribs, and may there in some cases be felt as a tumour." The condition is a mechanical result of great intrapleural pressure. The tumour is important in the differential diagnosis of abdominal masses. If the chest condition be overlooked or not correlated with the tumour error may arise. The tumour has a peculiar bulky feel, is tender, does not move with respiration, has the shape neither of the spleen nor kidney, and appears to have a deep attachment. Apart from paracentesis, X ray examination is probably the best means of diagnosis. The albuminous expectoration following paracentesis Dr. Riesman has ascribed to "congestion by recoil." It is very alarming and sometimes fatal. He has usually found that a hypodermic injection of morphine and atropine gives speedy relief, but, as in the case related, it may fail. The remarkable results of dry cupping must be due to some reflex nervous influence. Dr. Riesman believes dry cupping to be a good measure in all forms of acute pulmonary œdema, whether due to tapping or other causes.

HOURS OF LABOUR.

EVERY social student will recall the struggles of Oastler, Owen, Shaftesbury, and Cobbett in the first half of the nineteenth century which culminated in the Ten Hours Act, and the way in which that Act had to be strengthened in order to prevent the "relay system," under which the same person was illegally employed throughout two succeeding shifts. His thoughts will receive a sudden jolt when he notes that the Home Secretary has recently introduced a Bill permitting women and young persons to be employed in eight-hour shifts between 6 A.M. and 10 P.M. The reformers of the nineteenth century would consider this permission tantamount to encouraging the relay system again; but times have changed, and what was necessary to protect industry against itself in 1850 has now become an obsolete statute standing in the way of further advance. The Ten Hours Act, passed to ensure that the human machine was not worked more than ten hours a day, limited the working of the inanimate machine to the same period; but modern investigations have so established the economic folly of over-working humanity that the inanimate machine can be safely allowed to work for longer hours. This alteration in the law may pass unnoted, yet it marks a change of the utmost importance to the productivity of industry and to the health of the working-classes. It is, in effect, an Eight Hour Act; for although it applies only to women and young persons, many industries so depend on the work of these protected persons that their hours decide the hours of adult male labour. The Ten Hour Act in itself was an instance of the man gaining advantages behind the woman; and even if legislation was not under consideration for establishing a general eight-hour day, the statute now under contemplation would go far to establish this limit for industrial work. Lord Leverhulme has advanced the proposition that the object to-day should be, so far as hours of labour are concerned, to sweat the machine, not the worker. Machines, he points out, should be worked to their utmost while they are still of the latest pattern, and then give way to improvements. Otherwise industry becomes clogged with effete plant, and is less productive. His proposal for six-hour shifts cannot be fitted into the new statute; nevertheless, it marks an important advance. When full advantage is taken of the permission it gives, over-fatigue, and what arises from it, social unrest and ill-being, should be diminished among the industrial classes.

THE next session of the General Medical Council will commence at 2 P.M. on Tuesday, June 1st, when the President, Sir Donald MacAlister, will take the chair and give an address.

Mr. Norman G. Bennett has been appointed a member of the General Medical Council, on the nomination of the Privy Council, in succession to Sir Charles S. Tomes, whose term of office came to an end on May 20th.

A LIMITED number of commissions in the Regular Royal Army Medical Corps are being offered to officers who are at present serving in the army or who have held commissioned rank during the war. The conditions of service will be found fully stated on p. 1137.

WE remind our readers of the post-graduate course of study in the principles of balneology to be held at Bath between June 7th and 19th. This is the first serious attempt in this country to make extended use for teaching purposes of all the resources of a famous spa. Accommodation will be arranged for those attending, the number being strictly limited. The fee for the whole course is £5 5s., and application for tickets should be made to the Secretary of the Fellowship of Medicine, 1, Wimpole-street, London, W. 1.

THE dinner in celebration of the services of the Royal Army Medical Corps and the eminent civilians attached to it during the recent war will take place at the Connaught Rooms on Tuesday, June 8th. Lieutenant-General Sir Alfred Keogh, G.C.B., G.C.V.O., will be the chief guest, and among those who have accepted invitations to be present as Commanders of Armies are Field-Marshal Viscount French, Field-Marshal Earl Haig, Generals Lord Horne, Lord Rawlinson, Sir Ian Hamilton, and Sir Archibald Murray. The Right Hon. Winston Churchill and other members of the Army Council will be present. Some 40 hosts will preside at the different tables, the committee being Lord Derby, Lord Midleton, Lord Edmund Talbot, General Seely, Right Hon. H. J. Tennant, and Colonel Sir Edward Ward, to whom all communications should be addressed at 10, Grosvenor-street, London, W. 1.

A RED CROSS APPEAL.

THE British Red Cross Society and the Order of St. John of Jerusalem in England have issued through their joint council, of which Sir Arthur Stanley is the chairman, the following forcible appeal to the public to maintain for purposes of peace the magnificent support which was forthcoming during the war. The appeal, which is signed by H.M. Queen Alexandra as President of the British Red Cross Society, and the Duke of Connaught as Grand Prior of the Order of St. John, runs as follows:—

On the outbreak of war in 1914 there were two corporations authorised to engage in relief work among the sick and wounded men of His Majesty's Forces—viz., the British Red Cross Society and the Order of St. John of Jerusalem. These two bodies worked independently, but quickly came to the conclusion that everything must be done to coördinate their activities and to avoid waste and overlapping, and that to this end it was expedient to "pool" their funds and their efforts. A Joint War Committee was formed, together with a Joint Finance Committee, and it is under these two Committees that the voluntary work of relieving the sufferings of the sick and wounded men of His Majesty's Forces has been carried out during the past six years.

During that period a vast number of workers, both men and women, throughout the whole Empire, gave unwearying and devoted service to the cause, and it was natural that, when peace came, there should be a general feeling that an organisation such as this, founded on the voluntary efforts of those whose object was the relief of suffering and distress, should not be disbanded or allowed to disappear.

Moreover, there is still the aftermath of war to be dealt with. The Joint War Committee has been engaged since the armistice in carrying on certain of its war departments which deal with work that must continue for some time yet to come, such as the care of the sick and wounded men of His Majesty's Forces, whether still on the active list or demobilised; such care as may still be necessary for those who have been prisoners of war; assistance to orthopædic clinics and curative posts for the treatment of pensioners; home service ambulance organisation; Red Cross and St. John war and peace library.

There are also other branches of work which can usefully be undertaken in time of peace by the Order of St. John and the British Red Cross Society, such as the care of those suffering from tuberculosis, having regard in the first place to sailors and soldiers, whether they have contracted the disease on active service or not; assistance, financial and otherwise, to the voluntary civil hospitals, in view of the strain put upon these hospitals by the war; work parties to provide the necessary garments, &c., for hospitals and health institutions; child welfare work; assistance where required in all branches of nursing, health and welfare work, ancillary to the Ministry of Health.

The two corporations were anxious that these various branches of work should be carried on, and felt that for this purpose a governing body should be set up in place of the Joint War Committee, which had been created only for work in time of war. They have, therefore, by a formal agreement, established a Joint Council, on which both bodies have equal representation. This Council possesses under the old Charter of the Order of St. John and the newly extended Charter of the British Red Cross Society full power to act in all matters connected with "the improvement of health, the prevention of disease, and the mitigation of suffering throughout the world." (Extract from Article XXV. of the Covenant of the League of Nations.)

The Joint Council has now begun its work, and makes an earnest appeal to the public for a continuance of that great and munificent support which carried the Joint War Committee through the years of war. During those years the sick and wounded men of His Majesty's Forces learnt to look upon the Red Cross as an emblem, not only of help and comfort, but also of the devotion of the British people for the men who were fighting in Britain's cause. It is our earnest hope that those who, in peace time, are in suffering or distress, will learn in the same way to look to the White Cross of St. John and the Red Cross for comfort and relief, and will feel, when helped by the Order of St. John and the British Red Cross Society, that they are not receiving anything in the nature of charity, but only the just and proper tribute from those who are enjoying health and strength to their fellow men and women who are less fortunate than themselves.

For some branches of the work mentioned above—those in the first category—the Joint War Committee will continue to provide the necessary funds, either wholly or in part, for some time to come, but for all the other work of the Joint Council money is needed at once.

The greater the support that we receive from the public the better the work that we can do, and the more promptly we receive that support the sooner we can start our mission of healing and comfort. That is why we put forward this appeal, confident in the strength of our cause and in the generosity of the public that has never failed us yet.

Donations and subscriptions should be sent to the Joint Council Finance Committee, 19, Berkeley-street, London, W.1. Cheques should be crossed "Lloyds Bank, Ltd."

ALEXANDRA,
President of the British Red Cross Society.
ARTHUR,
Grand Prior of the Order of St. John of Jerusalem in England.

May 15th, 1920.

GENERAL SURVEY OF THE HOSPITAL SITUATION THROUGHOUT ENGLAND AND WALES.

By Sir NAPIER BURNETT, K.B.E., M.D.

Sir Arthur Stanley, chairman of the British Red Cross Society, at a meeting of the secretaries and house governors of the provincial hospitals, held at St. Thomas's Hospital on Jan. 23rd, 1920, intimated that if the voluntary hospitals would accept the assistance of the Joint Council of the Red Cross Society and the Order of St. John, then such work *would be embodied in the peace programme of the two* associations working jointly as they did during the war. The hospitals represented at the meeting gladly accepted this offer of the Red Cross, and thereafter it was decided to ascertain to what extent the hospitals were in difficulty, and this has been done by means of a survey. The object of the survey was twofold—namely, to show (*a*) something of the volume of work done by each individual hospital during the year 1919; and (*b*) the present financial position. The data set out below have been supplied either direct by the hospital secretary or abstracted from the hospital annual report.

THE SITUATION OF 550 PROVINCIAL HOSPITALS.

Throughout the 55 counties (England and Wales) 550 hospitals have been dealt with up to date, approximately 78 per cent. of the voluntary civil hospitals, omitting those dealing exclusively with tuberculosis. The voluntary hospitals in London are not included in the present survey, as it was felt that for many years the London hospitals have enjoyed the benefit of the great collecting organisations, such as King Edward's Hospital Fund, the Hospital Sunday Fund, the Hospital Saturday Fund, and the League of Mercy. The provincial hospitals have had no such central funds, and this fact suggested priority of assistance being given to these institutions.

TABULAR STATEMENT OF THE SURVEY.

A.—*Volume of Work Done.*

Of the 550 hospitals reviewed—
507 hospitals have 29,821 available beds.
498 hospitals treated 350,459 in-patients during the year.
376 hospitals treated 1,600,869 out-patients during the year.
296 hospitals with 23,621 beds had a daily average occupation of 18,705·36 beds (= 79 per cent.).
374 hospitals show 219,196 surgical operations during the year.
68 hospitals give figures showing the nature of cases treated—namely, medical cases, 7034 (21% of total); surgical cases, 26,466 (79% of total).

B.—*Financial Position.*

543 hospitals show ordinary income £2,835,269.
543 hospitals show ordinary expenditure £3,310,896.
Excess of expenditure over income, £475,627.

Some details of ordinary income:—
316 hospitals show as workmen's contributions, direct or through Saturday Fund, £451,426 (= 15·92% of ordinary income of 543 hospitals).
464 hospitals show as patients' contributions, £214,570 (= 7·56% of ordinary income of 543 hospitals).
248 hospitals show as Public Services (e.g., War Office, Pensions Ministry, Borough or County Councils), £517,890 (= 18·91% of ordinary income of 543 hospitals).
512 hospitals show as interest from investments, £423,044 (= 14·92% of ordinary income of 543 hospitals).
The total from these four sources, £1,606,930 (= 56·67% of ordinary income of 543 hospitals).

Of these 543 hospital accounts analysed—
449 hospitals show invested capital as £9,585,865, yielding annual interest £340,529.
66 hospitals show £33,706 as annual interest, but show no capital.
28 hospitals show no capital or interest.

DEPRECIATION OF INVESTED FUNDS.

9 hospitals show invested capital as	£306,956
Market value at end of 1919 being	£248,199
Depreciation in value	£58,757

This last item is shown merely in answer to a criticism that the hospitals in their present *financial* difficulty should realise some of their capital. Some few hospitals have actually been obliged to take this course, but only very few. The figures indicate that the hospitals cannot afford to unload their stock in the present state of the market.

In order to show the situation more clearly I have divided the hospitals into the following groups, namely —

Group A —Large General Hospitals of 100 beds or over
B —Medium-sized Hospitals of from 30 to 100 beds
C —Small or Cottage Hospitals of under 30 beds
D —Special Hospitals
F —Out-patient Clinics

Group	No of hospitals	No of beds	Average No of beds to each hospital	Total ordinary income	Total ordinary expend	Excess of expend over income	Excess of income over expend
A	82	15 958	194 60	£1 615 291	£1 970 976	£355 685	—
B	87	4 724	54 29	£436 331	£476 049	£39 718	—
C	240	3 355	13 97	£289 489	£276 855	—	£12 634
D	98	5 784	59 02	£458 309	£540 227	£81 918	—
F	Dispensaries 43	New out-patients 165 159		£51 838	£50 598	—	£1 240

COMMENTS ON THE SURVEY FIGURES

The figures brought out in the survey may be regarded as dealing with 'the facts' of the situation, and are issued as a first instalment dealing with some 550 hospitals—or approximately 78 per cent of all provincial hospitals—a sufficiently broad basis to draw conclusions from Further details will be published at a later date showing more particularly the voluntary hospitals, with their figures in each individual county in reference to population &c

Two additional figures, not shown in the above statement were taken out, namely —(*a*) the average length of stay in hospital of each in patient, (*b*) the average annual cost per occupied bed

The methods employed by some of the hospitals in ascertaining these data varied so much that I had no option but to discard the results For example, some hospitals included their "tonsil and adenoid' cases—usually in hospital only 24 hours—while other hospitals excluded these in arriving at their "average length of stay" figure Again, in regard to ' cost per occupied bed" I found that some hospitals included the cost of out patients, while others deducted such expenditure so that I concluded the figures for purposes of comparison, were unreliable

The volume of work done at the 550 hospitals reviewed shows that approximately 2 million patients received treatment during the year The figure shown for out patients indicates individual cases, and is not merely a record of "attendances"

During the war, owing to depleted clerical staff many of the hospitals allowed certain details to lapse from their records Hence it is that only 296 of the 550 hospitals give the "average daily occupation of beds", but where it has been given it reveals the high occupation of 79 per cent This is undoubtedly high when taken for the whole year, during part of which as a rule, some ward or wards are closed for cleaning or disinfection purposes

A further testimony of the enormous volume of work done in these hospitals is seen in the figure of 219 196 surgical operations during the year These included both major and minor operations where an anæsthetic has been employed but do not include dental operations

One other interesting figure is shown under the ratio of medical to surgical cases treated It is true that only some 68 hospitals give these figures, but they are sufficiently numerous as to indicate a present-day tendency towards catering for surgical work

Turning to the financial position, it will be seen that the excess of expenditure over income for the hospitals under review amounts to £475 627 Approximately 75 per cent of this deficit belongs to the large general hospitals of 100 beds or over, of which there are 82 in number It would appear from these figures that big hospitals situate in the populous industrial centres are supplying a much larger service than is recognised by the local communities The classification of the hospitals reviewed into groups according to their number of beds brings out more clearly the financial position

The difficulties at present being experienced by the voluntary hospitals may be grouped under the three headings—namely, (*a*) need of increased financial support (*b*) need of increased bed accommodation, (*c*) need of increased supply of nurses

Appended hereto is a suggested scheme for assisting the voluntary civil hospitals

OUTLINE OF SCHEME FOR ASSISTING THE VOLUNTARY CIVIL HOSPITALS

1 Hospital survey, to consist of—

(*a*) Data showing the volume of work done during the year 1919 in each individual hospital

(*b*) The financial statement of each hospital showing ordinary income and expenditure invested funds annual cost per bed &c

(*c*) Showing by maps the hospital situation in each county in ratio of beds to population

2 Public appeal for funds £1 000 000 per annum being aimed at The money, it is hoped, will be raised from the following sources, viz —

(*a*) Public appeal through the press &c for individual subscriptions

(*b*) Public appeal and personal canvass of business firms pointing out to commercial organisations the point of view that by setting aside each year a certain sum of money for distribution amongst charities may be regarded as a reasonable tax on industry and that by handing such sums to the Red Cross organisation for distribution they may be assured that the money will be distributed where it is most needed or if ear marked for certain districts it will be so distributed and thus relieve the business man of the uncertainty of knowing who is in most need of his support

(*c*) Public appeal through the great national collecting agency known during the war as Our Day organisation

The allocation of grants to hospitals will be made by a Grants Committee, on the recommendation of the Director of Hospital Services after investigation of such matters as—

(*a*) The efficiency of the hospital administration
(*b*) How far the hospital is meeting the needs of the locality
(*c*) As to its buying on scientific lines prices paid &c
(*d*) As to adequate payment of its nursing staff always provided that the standard of training is of the highest

3 Coöperative buying of hospital commodities

4 Coordinating the hospitals into groups in counties or other areas In every county or district there is the large central hospital which may be called the "key" hospital and it is hoped to arrange with the smaller county and cottage hospitals to become coordinated with the key hospital by having a working arrangement as to—

(*a*) Transport of patients

(*b*) The central hospital to receive severe cases from the smaller hospitals and return of slighter cases to the cottage hospitals and convalescent homes

(*c*) All pathological and bacteriological work of each group of hospitals to be arranged for at the central hospital No hospital would receive a grant from the Joint Council unless some such arrangements for the investigation of disease existed

5 Circulation of statistical and other hospital information from the Central Bureau

6 Convalescent hospitals —To give every encouragement for the establishment of convalescent hospitals in the country for the dual purpose of pre hospital and post hospital care

7 Meetings to be arranged in each county with the object of disseminating knowledge and stimulating interest in all matters pertaining to public health

By means of some such scheme as that outlined above, it is hoped to assist in the development of a national coördinated hospital system for the cure and prevention of disease

May 1920

SMALL POX AND ITS PREVENTION

THE ever present danger of small pox is being brought home to us by the outbreak which has occurred in the Glasgow district and which threatens to become epidemic in Scotland The first case sickened towards the end of February, and by May 12th 130 cases had been notified in Glasgow itself, 9 other cases in the west and 2 in the east of Scotland New cases are now occurring in Glasgow at the rate of about 10 a day A reference to the Urban Vital Statistics on p 1134 shows nine deaths in the week ended May 15th The type of disease is severe, with marked fatality among the unvaccinated, and, it may be assumed, with infectivity broadly corresponding to the severity The Scottish Board of Health fears a wide dissemination of the disease owing to the passenger traffic between Glasgow and other parts of the country which will be greatly enhanced during the coming holiday months The fact that a high percentage of the population under 13 years of age is unvaccinated (it was in 1907 that the conscientious objection clause was incorporated in the Vaccination Acts) is causing the Board grave anxiety

Under these circumstances it is a matter for congratulation that the problem of small pox in many of its aspects has recently been studied afresh by experts such as Dr J C McVail and Colonel W G King, I M S, whose conclusions are available for our help in present emergency In his paper on "Small pox and its Prevention," read before the Society of Tropical Medicine and Hygiene on Feb 20th and now reprinted, Colonel

---

* This scheme and a scheme for other work were set out in the peace programme of the Joint Council of British Red Cross and Order of St John

King draws attention to the widespread distribution of the disease throughout the world in both temperate and tropical climates. He further brings out in connexion with the pandemicity of small-pox the probability, hitherto but little recognised, of the existence of types and strains of differing virulence in various parts of the world. The changing virulence in different epidemics has, of course, long been known.

Types and Strains.

In the first of his Milroy lectures, delivered in March, 1919, and since conveniently republished in book form,[1] Dr. McVail made a very careful study of the principal types of infection with their differing morbidity and fatality, which should be read afresh at this juncture.

From extensive data Colonel King summarises the evidence as pointing to grades of virulence of small-pox under two types or parent stocks, two strains, descendants of the parent stocks, and one substrain.

1. The Eastern type, representing the most virulent strain and found east of longitude 40° E. and between 40° N. and 6° S., where amongst Asiatic populations the general fatality rate from the disease ranges from 33 to 50 per cent., in the vaccinated of all ages from 30 to 60 per cent. and in the unvaccinated from 60 to 80 per cent.

(i.).—Western strain, which has lost much of the virulence of its parent, the Eastern type, by gradual transference from Asiatic races and tropical conditions, and is found to the west of longitude 40° E., extending throughout parts of the world largely inhabited by Europeans and their descendants. The general fatality of this strain in pre-vaccination days varied from 18 to 25, but since this period, in the vaccinated from 1 to 5 and in the unvaccinated from 19·3 to 47 per cent.

(i.) *a.*—The Western substrain is taken to prevail over Norway, Sweden, Denmark, the British Isles, France, Switzerland, Belgium, Holland, and Germany—countries in which, the case of Belgium excepted, vaccination is carried out more or less consistently; and whereas the general fatality rate is lower than in any part of the world affected by the Eastern type or its Western strain, the existence of this substrain deserves recognition. Within the area of this substrain the virulent Eastern type fails, in the course of several transmissions, to preserve its original virulence.

2. A second type of small-pox, with a general case-fatality of 3·8 to 4·3 per cent., is recognised in South Africa, designated the "amaas" type, and characterised by its mild constitutional symptoms from both the Eastern type and the Western strain.

(ii.).—It is probable that from this mild type a strain of still less virulence has been derived, known as the "amaas" strain, and showing itself in races of European origin in America, in Canada with a general fatality rate of about 1·8 per cent., and in Australia of less than one per mille.

Doubtless the recently described "alastrim" belongs to this strain.

Is Small-pox Dying Out?

The existence of types of small-pox as pointed out by Dr. McVail is deserving of important recognition, if only to controvert the danger of falling into line with the statement emanating from Dr. C. K. Millard that small-pox, so far as this country is concerned, is dying out. Such a statement Colonel King rightly emphasises as likely to be seized upon by the antivaccinist; it might, indeed, well lead to a disastrous relaxation of our means of protection by vaccination, if such a point has not already been reached. It cannot be gainsaid that, particularly in the poorer quarters of the London area, a large proportion of the young population are growing up unvaccinated, and likely to provide a ready soil for the outbreak of a serious epidemic in the presence of a mild or unrecognised focus of infection.

An example of the possibility of such a spread is supplied by the concise account of the dissemination of the disease, contained in the paper by Captain G. G. Johnstone, who describes in the present issue of THE LANCET an outbreak of small-pox in the part of Germany occupied by the British army. But for the activities of the British military authorities in insisting on vigorous isolation of patients and contacts and the general vaccination of inhabitants, the spread of infection might well have covered a very extensive area and dangerously hampered the occupying troops.

Colonel King attempts to reconcile the divergent opinions expressed by Dr. Millard and Dr. McVail. The former of these two in his belief that small-pox in this country is dying out advocates the application of the "Leicester method," which neglects to enforce infantile vaccination, and trusts to careful segregation of cases and sanitary measures with vaccination of contacts. Dr. McVail, while regarding the neglect of infantile vaccination as dangerous in view of the impossibility of forecasting the incidence and type of the disease which may become prevalent, also comes to the conclusion that a great diminution in the infectivity, fatality, and prevalence of small-pox has taken place in Great Britain during the last 50 years, but attributes this to the advent of two different types—the North African and American—the probability of which is demonstrated during the period 1902 to 1905, when in London the North African type prevailed, with a mortality of 16·8 per cent. in 9659 cases, whereas in the provinces, where the milder American type was dominant, the rate was only 6·9 per cent. in 23,883 cases. The transit of the North African type to London is readily accounted for by the easy communication between Tunis (with its mortality rate of 40·4 per cent.) and Marseilles (41·4 per cent.), and thence to Paris.

The uncertainty as to the type of disease which may become prevalent, particularly under conditions now existing in the wake of the war and the impossibility of forecasting its infectivity in the face of large numbers of unvaccinated young people, are matters which cannot be neglected nor their attendant risks exaggerated. The elasticity of the legislation controlling vaccination and the unwise exemption granted to conscientious objection demand urgent revision of the whole subject in its bearing on national prophylaxis.

Colonel King quotes convincing arguments against the application of the "Leicester method," particularly in the tropics, instancing the influence of vaccination in Calcutta in five years preceding 1914. The Gloucester epidemic of 1896 referred to, also provides ample proof of the inefficacy of segregation without vaccination. He maintains that there is no reason to believe that small-pox is dying out in consequence of modern sanitary conditions—a result which would not necessarily be confined to Great Britain.

Geographical Distribution of Small-pox.

The valuable and instructive map of the world accompanying Colonel King's paper affords a graphic means of recognising the distribution of the *particular types* and strains, together with their comparative virulence and fatality rates drawn from the largest and most reliable data, and confined to the period of, and subsequent to, 1902.

The countries where vaccination is compulsory, where compulsion is well exercised, where vaccination receives official recognition but is not legally enforced, and where enforced in special areas, are designated by distinctive markings. From these much may be learnt—e.g., the fact that in Belgium, where vaccination is merely recommended, the fatality rate is 16·3, and in Luxembourg 19·7, whereas in France and Holland, on either side, both countries well vaccinated, the rates are only 8·4 and 8·7 respectively.

Interesting conclusions are also drawn from this map:—

1. As to possible modes of transference of the disease from country to country. Such are obvious in the passage of travellers during incubation, by trade and pilgrim land routes and by shipping routes through seaports within a 12 days' period.

2. In the influence of climate on the virus Duncan Stewart is quoted as concisely defining the conditions under which its diffusion is favoured by dry and cold weather and adversely by damp heat—factors which govern equally the vitality of the vaccine.

3. Individual peculiarities of families, communities, and races, known to exist both in their susceptibility to the disease and their response to vaccination, may well influence an epidemic outbreak and enable a weakly strain of small-pox to regain its virulence when implanted on a susceptible soil.

4. The influence of a low grade of personal and sanitary hygiene renders possible the harmful action of associated organisms in aggravating the variolous skin lesions and in

---

[1] Half a Century of Small-pox and Vaccination. Edinburgh: E. and S. Livingstone. Price 5*s.* 6*d.*

increasing the destructive properties of the virus, thus favouring the most virulent form of the disease Accident or neglect of proper precautions in vaccination may, for the same reason increase the local inflammatory reaction The beneficial effect of improved sanitation, it is suggested may be due to the limitation of extraneous and associated organisms, and consequently lead to a diminution in extent of the small pox lesion Conversely, it is deduced that the introduction of small pox of a mild type among people of low vitality in filthy and overcrowded conditions will result in a raising of virulence of the disease The variation in virulence of small pox epidemics has long been recognised and may be due to such factors producing an increase of or impairment of resistance to disease

5 Attenuation in virulence of small pox may be expected to occur when introduced into a community whose resistance has been raised in whole or in part by vaccination For ample evidence is claimed to show that a beneficial modifying action persists as a result of infantile vaccination even in the absence of revaccination

The facts as to the power of vaccination to protect the individual and prevent the spread of infection in the community are so clear as, Colonel King states, to need *no emphasis*, those bearing on the duration of immunity afforded by vaccination or an actual attack of small pox are however, far from attaining definition, albeit statistics would seem to show that the vigorous age of life may afford to vaccinated and unvaccinated alike a better chance of resistance than at the early or late periods of life, but failing protection by means of previous small pox, inoculation, or vaccination, all ages are equally susceptible to attack

Revaccination

As experience of the disease grows in both temperate and tropical countries the period of protection conferred by a primary vaccination has, Colonel King states, gradually diminished, and evidence shows that in the case of those vaccinated in early life the incidence and fatality of small pox increase with advance of age—e g the susceptibility of the aged inmates of the almshouse at St Vith, as recorded in Captain Johnstone s paper The necessity for revaccination was recognised by the Government in Madras so long as 1894, and, as is of course well known, is acted on and strictly carried out in our services Such examples should materially assist in educating public opinion in this direction, and lead to a realisation of the importance of the legislation in force in France, also in Prussia since 1874 by which revaccination is secured at puberty

Vaccine Institutes and Vaccine Stock

Considerable attention is devoted by Colonel King to the great importance of the provision of vaccine institutes, particularly in tropical climates, with special regard to the requirements of the tropics and essential equipment for the maintenance of strict asepsis and preparation of vaccine by properly trained staffs He emphasises the necessity of maintaining the vaccine used in the tropics in a high state of activity, and, bearing on this need, contends that as the Eastern type of disease is possessed of much greater and more deadly virulence than the Western a relation exists between this virulence and the case fatality not only in the unvaccinated but in the degree of immunity from death conferred by vaccination in the case of those infected by the Western type when compared with those attacked by the Eastern type He quotes tables in support of this belief, and claims that so formidable a type as the Eastern calls for the use of a very special vaccine, for its virulence is deadly even among the vaccinated He points out that the question of the origin of vaccine or of the true nature of the *causa causans* of small pox is in danger of being indefinitely shelved and that the degeneration or death of a vaccine stock, despite the most favourable conditions prevailing, may occur as the result of accident or unforeseen circumstances Considerable controversy has raged in time past on the subject of vaccine stock and when Ceely, in 1839, and others subsequently, secured stocks by direct inoculation of bovines by the use of both vaccine and small pox virus on different but closely adjacent sites Doubts were raised as to the genuineness of these results and those of Voigt at a later date in 1881 It remained for Simpson, in 1884, to close the controversy by successfully securing undoubted variola vaccine stock through direct inoculation of a bovine with small pox virus, and by the use of this stock for the vaccination of 1200 infants without untoward result In dealing at length with the question of vaccine stock Colonel King describes another recognised source in the disease as it appears in bovines (cow pox), and the process by which degenerated vaccine may be rejuvenated He supports the method of obtaining variola vaccine stock by the inoculation of bovines with vaccine and small pox virus as sound and certain, and is further of opinion that the mode of rejuvenating vaccine is possible by utilising an animal which has been regarded as of no further use for the purpose, but where an attempt to get variola vaccine has been made with simple variolation without vesiculation resulting The use of intravenous injection is dwelt upon as a likely means in future of securing certainty as to the sufficiency of the dose of small pox to obtain vesiculation in bovines Such a method of vaccination is suggested by a quoted writer as applicable to the human being, once the dose is established, and likely, without *any prolonged disability or discomfort*, to confer immunity covering a very long period

The Dual Nature of Small pox

Support is lent to the view originally expressed by Simpson in 1892 as to the dual nature of small pox, and to the suggestion of others, at a later date, that symbiosis plays a part in vaccine production The suggestion made that, if the Chinese have successfully caused small pox to be communicated by blowing scabs into the nostrils, this dual nature may be due, as possibly in the case of influenza, to an ultramicroscopic organism, and its requiring a symbiosis for full virulence, opens the ground for plentiful discussion

Vaccination Departments

Granted the supply of vaccine in an active condition and in quantity sufficient for primary vaccination, revaccination, and epidemic emergencies, it next devolves to ensure use of the vaccine to the best advantage This, Colonel King rightly maintains, " can only be secured by determining to utilise well educated and reasonably paid men " in staffing the vaccination departments—e g , sanitary inspectors who in addition to a course of training in hygiene, physiology, and bacteriological demonstrations, undergo periodical examinations and a three months course in all that appertains to human and animal vaccination, in order to become vaccinators and deputy inspectors of vaccination under the supervision of a special medical officer

Sanitary Organisation against Small pox

The Scottish Board of Health in a recent circular impresses upon medical practitioners the need for close cooperation with the public health departments in their efforts to prevent the spread of the disease, with a view to securing early diagnosis in suspected cases Communication with the medical officer of health of the area at the earliest moment is imperative in order that, should suspicion be confirmed, all necessary precautions may be taken pending removal to hospital Where no doubt exists as to the diagnosis the patient and all immediate contacts are warned to remain where seen until the arrival of the sanitary officials The danger to others of infected persons travelling by car or other public vehicle is always to be kept in view and impressed on patients

Colonel King's highly important contribution to the subject of small pox and its prevention concludes with a well advised note on sanitary organisation which, he says, should be directed to securing instant intelligence of attacks and prevention of spread of infection He emphasises the call for vaccination as the first line of defence with sanitation available as a reserve as soon as danger threatens

The experience of the Scottish Board of Health suggests that the protection which successful vaccination affords is not sought by the population at large until a wholesale dread of contracting small pox arises from the actual proximity of the disease and the occurrence of deaths as a result of it The general practitioner can render invaluable assistance not only in vaccinating those who desire to be vaccinated, but by persuading all those with whom his work brings him in contact—and especially the parents or guardians of unvaccinated children—to have the operation performed without delay.

As no country can be said to be free from invasion in the presence of a pandemic disease, legislation should be possible to prevent the passage of persons from one country to another unless freedom from communicable disease is assured. Such a principle should apply particularly to aliens seeking labour in tropical countries and the guarantee be required of recent vaccination. Colonel King further draws attention to the necessity of the British Empire awaking to the importance of the example in force in the public health service of America, by placing special officers at the chief foreign ports, and elsewhere trusting to consuls, to maintain touch of diseases throughout the world. Professor E. W. Hope in this connexion is quoted as forcibly proclaiming the error of ignoring the necessity for bringing the pandemic disease of small-pox within the scope of an international convention. Such a step can alone rouse us from the sense of false security, short of a severe and widespread outbreak for which the increasing number of unvaccinated persons in this country and elsewhere is smoothing the way.

THE ROYAL SOCIETY CONVERSAZIONE.

WHILE the exhibits at the conversazione of the Royal Society, held on Wednesday evening, May 12th, were not so numerous as on pre-war occasions, they were of considerable interest, covering many scientific fields, though medicine was represented in few direct ways. Pure science seems to have held first claim to parade, but the opportunity seems to have been missed of presenting examples of the fruits of advice given by the Society to the Government through the war. Nor were there any illustrations of the advances made by a coöperation of university activities with those of the factory.

Fluorescence, Osmotic Processes, and Synthetics.

A very fascinating demonstration was that of fluorescence in Lepidoptera by ultra-violet radiation by Dr. J. C. Mottram and Dr. E. A. Cockayne. These investigators employed filtered light from a mercury-vapour lamp, using only radiations of certain wave-lengths. When exposed to these rays and viewed, of course, in the dark, the fluorescence of the wings of butterflies and moths was most remarkable, some more brilliant than others resembling a bright opal matrix under the most favourable conditions. This curious analysis of light (we must remember white light is a composite of primary colours) can be exhibited to some extent in a solution of the wings of certain species in glacial acetic acid.

Close by, an interesting document was shown: the original letter of Priestley which in 1779 announced the discovery that plants give off oxygen.

Osmosed clay easily enough may have medical significance. Specimens of this were shown by the Osmosis Company, Ltd. So far the process has been applied to the purification and decolorising of china clay for the manufacture of paper and clean fire-clays, and the results are of the most encouraging description. The process is based on an electrolytic selective action.

The only exhibit illustrating a captured industry was that of Messrs. J. Crosfield and Sons, Ltd., who showed an attractive series of synthetic products for perfumery formerly elaborated entirely in foreign countries. The manufacture was installed owing to the difficulty, in some cases impossibility, of obtaining such products during the war.

Bacterial Photography, Mites, Fleas, and Vitamines.

There was an interesting series on view in the Council Room of photomicrographs obtained by means of ultra-violet light by Mr. J. E. Barnard. An important advantage of employing ultra-violet light for this purpose in microscopical work is that biological preparations, particularly bacteria and other micro-organisms, are rendered sufficiently opaque to ultra-violet light of suitable wave-length to render staining unnecessary. This appears to open up a very promising field of investigation, for by this method micro-organisms can be photographed in the living state.

Professor R. Newstead exhibited samples of mite-infested flour, which illustrates the importance of preventing mite invasion. When this happens the flour is ruined, and develops a most unpleasant odour and becomes discoloured owing to the quantities of excrement with which it is charged. A high moisture content invites invasion.

Professor G. H. F. Nuttall and Dr. D. Keilin exhibited microscopic specimens illustrating hermaphrodites of inter-sexual type in *Pediculus humanus.* The exhibit comprised a complete series of forms from those of male type to those of female type, the coexisting characters of both sexes being present to a varying degree. It is pointed out that the inter-sexual forms which occur among pediculi in nature are derived from the crossing of the races *of P. humanus*—i.e., capitis and corporis. Some of these crosses yield up to 20 per cent. of hermaphrodites, and the appearance of hermaphrodites in a given stock is always accompanied by a great decrease or almost complete disappearance of females.

Professor E. Mellanby, whose work on the subject is familiar to our readers through our columns, gave striking illustrations of the effect of the absence of an accessory food factor (probably fat-soluble A) in the diet of puppies which developed rickets. The investigation by Mrs. Mellanby also demonstrated that diets deficient in an accessory food factor, possibly fat-soluble A, produce teeth defectively calcified and more or less irregularly placed in soft jaws. Referring to teeth, Dr. J. H. Mummery, in a demonstration of the nerve end-cells in the pulp of the human tooth, pointed out that the mode of distribution of sensory nerves in the pulp of the tooth was not met elsewhere in the body.

Frog Metamorphosis, Plant Respiration, and Wireless Telephony.

The influence of thyroid feeding on the frog was instanced in the exhibit of Mr. Julian Huxley and Mr. Lancelot T. Hogben. There were examples of (1) acceleration of a frog's metamorphosis by thyroid feeding; (2) metamorphic changes induced by iodine; and (3) metamorphosis of amblystoma by thyroid feeding with a control.

A quite interesting demonstration of an ingenious apparatus recording the rate at which air under slightly reduced pressure is drawn through the pores of a leaf was given under the direction of the Botany Department of the Imperial College of Science and Technology. This recording porometer gives a measure of the size of the pores, which varies for different leaves. It is of interest also to mention the system described by Mr. Edwin Edser of concentrating minerals and coal by froth flotation. Shortly, this is done by adding water to the low-grade mineral, which is reduced to a fine state, then forcing a stream of minute bubbles of air through the fluid, which brings the valuable material to the surface, which can be skimmed off. The barren material, rock or slate, is not floated.

Lastly should be mentioned as a modern wonder the demonstration of wireless telephony given in the meeting room. The audience here heard plainly in all parts of the room a musical performance being given 30 miles away (Chelmsford). The loud-speaking telephone had no communication with that place except by the all-pervading ether; there were no wires, no pipes—in a word, no visible means of transmission at all.

Sir J. J. Thomson, the President, received a large company of distinguished guests.

DONATIONS AND BEQUESTS.—The Chelsea Hospital for Women has received a grant of £400 from the trustees of the Zunz Bequest.—The Royal Dental Hospital of London has received a donation of £500 from the trustees of Smith's (Kensington Estate) Charity.

SCOTLAND

(FROM OUR OWN CORRESPONDENTS)

Aberdeen Hospitals Scheme

AT a meeting of the Aberdeen University Court held on May 11th the following resolutions were unanimously adopted —

> Having considered the resolutions of the Aberdeen Medico-Chirurgical Society passed in conference with other members of the medical profession in the North of Scotland on March 16th and having heard the exposition of the same made by Professor Ashley Mackintosh at a conference in the Town House of the public bodies concerned on April 19th the Court now resolves to express its agreement—
>
> (*a*) With resolution 1 on the growing and clamant need in Aberdeen for largely increased hospital accommodation of the most modern type in order adequately to meet the requirements of the city and the North of Scotland especially in regard to the Royal Hospital for Sick Children and the Royal Infirmary
>
> (*b*) With resolution 2 that these requirements cannot suitably be met by any extension of these hospitals on their present sites or in their immediate vicinity and
>
> (*c*) That the substance of resolution 3—namely not only that the concentration of these hospitals upon a common site on which their extension from time to time would be possible is very desirable but that in view of all the circumstances the present is an opportune time for taking the initial step towards that end Further the Court resolves to express its opinion that should such combination of the hospital be carried out it would be in the interests of medical education as well as of the patients if certain departments of medical instruction and research in the University were removed as opportunity might offer to the same site

At a meeting of the Aberdeen Royal Infirmary Board held on May 12th the board, after consideration of the resolutions of the Aberdeen Medico Chirurgical Society, passed at its meeting on March 10th last, and submitted and explained by Professor Ashley Mackintosh at the conference of public bodies interested, held in the Town House on April 20th last, resolved that, to enable them to lay the proposals suggested in the society s resolutions before the managers for their consideration, it was desirable that further conferences should proceed between the public bodies interested in order that the financial and other aspects of the scheme should be considered, with a view to determining its practicability The board approved of the chairman attending any further conferences

Aberdeen University Appointments

At a meeting of the Aberdeen University Court, held on May 12th, Mr J Scott Riddell was appointed external examiner in surgery for the degree examinations which are to be held at the end of the present term It was agreed to appoint a lecturer in anatomy at a salary of £400 a year

Small pox in Glasgow Memorandum on the Value of Vaccination

In view of the increasing prevalence of small pox in Glasgow and neighbourhood, the Council of the Royal Faculty of Physicians and Surgeons issued on Saturday last, through the local press, a reasoned statement of the value of vaccination as a protection against small pox After briefly reviewing the appointment of the Royal Commission in 1889 and the main conclusions to which it came, the gist of Section 503 is quoted —

> We can see nothing to warrant the conclusion that in this country vaccination might safely be abandoned and replaced by a system of isolation What [isolation] can accomplish as an auxiliary to vaccination is one thing whether it can be relied on in its stead is quite another

The Memorandum concludes with the following summary of the events of the 1900/02 epidemic of small pox in Glasgow —

> The value of effective recent vaccination was amply illustrated in local experience during the prevalence of the disease in Glasgow which began in 1900 Early in 1901 the committee on health offered free vaccination on a wide scale and ultimately over 400 000 of the population availed themselves of the offer Not one case of small pox occurred among this number All the cases of the disease which did occur—over 1800—were drawn from those who had not accepted the offer We think it impossible to over-emphasise this demonstration of the value of recent vaccination It is strengthened by the experience of the small pox hospital itself The medical and nursing staff numbered 80 all were efficiently vaccinated and none contracted the disease although in daily contact with it Fifty hospital servants had a like experience For purposes of clinical instruction in the disease 150 practitioners and students of medicine visited the hospital It was a condition of admission that they should be vaccinated beforehand none contracted infection It was necessary to extend the hospital during the outbreak and 230 workmen were employed 217 accepted revaccination and none of these contracted the disease 13 refused vaccination or for some other reason were not recently vaccinated 5 of the 13 contracted the disease and 1 died

Dr A Freeland Fergus, President of the Faculty, and other medical men who signed the Memorandum, state that collectively they regard these facts as completely establishing the protective value of vaccination

At the recent monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, James Devon, *L R C P Edin*, *&c*, *Alexander Morton*, *M D*, *and* Edward James Primrose, M D , B Sc , were admitted as Fellows of the Faculty

The Glasgow University Club will dine at the Holborn Restaurant London on Friday, June 4th, at 7 30 P M , the Right Hon A Bonar Law, Lord Privy Seal and Lord Rector of the University, in the chair All communications should be made to Dr Alex Macphail, honorary secretary, at St Bartholomew s Hospital, London E C 1

May 17th

PARIS

(FROM OUR OWN CORRESPONDENT)

Influenza Statistics

THE municipal registration office has just issued a full report on the statistics of last year s epidemic of influenza Apparently the epidemic was more serious than was thought and more serious also than was shown by the actual death rate 3098 men and 5377 women died in Paris of influenza, which attacked principally healthy adults, and was especially virulent in the case *of women from 20 to 40 years old, whose mortality* is given at the amazing figure of five times the average influenza mortality

Institute of Hygiene in the University of Paris

An institute designed to train specialists in this branch of medicine and to centralise the laboratories of allied subjects is apparently soon to be established An agreement has been arrived at between M Breton, the head of the new Ministry of Hygiene, and the Ministry of Public Instruction, represented by M Roger, dean of the Faculty of Medicine As a matter of fact the teaching of hygiene is already well organised, with theoretical and practical classes, at the Faculty of Medicine There is no question of supplanting these courses It can, nevertheless, be foreseen that the two organisations will inevitably overlap, with resulting unnecessary increase of expense in upkeep, personnel, and buildings M Hayem had suggested to the Academy of Medicine that it would be possible to economise considerably by taking over the already existing well appointed Institute of Hygiene established by the *Germans at Strasbourg, but the professor of the Faculty* of Hygiene at Paris brought up a number of objections and claimed an institute for Paris If public hygiene depended merely on the number of establishments created and on the amount of money laid out, its advance in Paris would be assured

The Association of the Presse Médicale Française

This association has recently held an election, the terms of office of the presidents M Albert Robin and M Marcel Baudouin having expired Dr Raoul Blondel, director of the *Revue Thérapeutique*, and Dr La Sourd, editor of the *Gazette des Hôpitaux*, and, to represent the provincial press, Dr Monprofit, of Angers, have been elected presidents

May 17th

THE Mayor of Volksrust, Transvaal, presided at a dinner held recently in honour of Dr W J Watt local medical officer of health and South African Railway surgeon The company was a very representative one, and Dr Watt was accorded many demonstrations of the goodwill and regard in which he is held by the community of this important district The evening concluded with the presentation of a well filled purse the gift of a wide circle of friends

The personnel of public health authorities concerned in the supervision of these examinations and of the analytical work involved remains the same as published in previous tables. The analyses of the rain and deposit caught in the gauge at the Meteorological Office are made in THE LANCET Laboratory.

There were no returns from the following stations during the month of December, 1919: Victoria Park (London), Malvern, and Manchester, while at one station in Glasgow (Ruchill Park) an accident happened to the collecting bottle, and at Stirling the bottles were broken by frost. There was again lead present in the deposit of the Glasgow samples. In January, 1920, there were no returns from the following stations: Ravenscourt Park (London), Stirling, and Manchester. Evidence of contamination from the fittings of the gauge is reported from the south-western station at Birmingham. The gauge at the observation station on the London Embankment Gardens has been transferred to Archbishop's Park. Lead was again reported in the deposit of the Glasgow samples.

URBAN VITAL STATISTICS.

(Week ended May 15th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had declined from 18·7 to 13·8 in the seven preceding weeks, was again 13·8 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 12·5, or 0·5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 5·0 in Southend-on-Sea, 6·4 in Ealing, and 6·6 in Edmonton, to 23·3 in Wigan, 26·6 in Sheffield, and 28·8 in Tynemouth. The principal epidemic diseases caused 339 deaths, which corresponded to an annual rate of 1·0 per 1000, and comprised 116 from measles, 78 from whooping-cough, 75 from infantile diarrhœa, 41 from diphtheria, 20 from scarlet fever, and 9 from enteric fever. Measles caused a death-rate of 1·6 in Brighton and in Swansea, 1·7 in Walsall, 2·4 in Wigan, 3·8 in Rhondda, and 3·9 in Norwich, and whooping-cough of 2·4 in Darlington. The deaths from influenza, which had steadily declined from 392 to 201 in the seven preceding weeks, rose to 216, and included 51 in Sheffield, 32 in London, 10 in Newcastle-on-Tyne, and 9 in Manchester. There were 1916 cases of diphtheria, 1757 of scarlet fever, and 6 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospitals, against 1947, 1794, and 11 respectively at the end of the previous week. The causes of 41 of the 4708 deaths in the 96 towns were uncertified, of which 8 were registered in Liverpool, 7 in Birmingham, and 3 each in Stoke-on-Trent and Manchester.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had been 19·2, 18·3, and 18·4 in the three preceding weeks, fell to 16·9 per 1000. The 397 deaths in Glasgow corresponded to an annual rate of 18·6 per 1000, and included 27 from measles, 22 from influenza, 9 from small-pox, 4 each from diphtheria and infantile diarrhœa, and 2 from whooping-cough. The 79 deaths in Edinburgh were equal to a rate of 12·1 per 1000, and included 5 from influenza and 1 each from diphtheria and infantile diarrhœa.

Irish Towns.—The 164 deaths in Dublin corresponded to an annual rate of 20·6, or 2·3 per 1000 below that recorded in the previous week, and included 11 from measles, 10 from whooping-cough, and 1 each from infantile diarrhœa and influenza. The 134 deaths in Belfast were equal to a rate of 16·9 per 1000, and included 8 from influenza, 6 from infantile diarrhœa, and 1 from whooping-cough.

UNIVERSITY OF LIVERPOOL.—Messrs. Alfred Holt and Co. have given £15,000 to the Liverpool University Appeal Fund. The Association of West African Merchants and the African Section of the Chamber of Commerce are raising £12,000 by voluntary collection from their members to provide a Chair of Colonial Commerce, Administration, and History at Liverpool University, and to increase the endowments of the Liverpool School of Tropical Medicine.

"Audi alteram partem"

THE GENERAL PRACTITIONER AND THE TREATMENT OF TUBERCULOSIS

To the Editor of THE LANCET

SIR,—At the present time, with thousands of cases of tuberculosis among discharged soldiers entitled to medical care and treatment at the hands of the Public Health Service, we find ourselves confronted by the fact that practically nowhere will general hospitals admit this class of patients Moreover, there is almost everywhere throughout the United States a lamentable shortage of hospital facilities for those ill with tuberculosis *The opening of general hospitals to this class* of patients would do very much more than provide relief for a large class of unfortunates it would undoubtedly contribute enormously to the efforts now being made to control tuberculosis

As conditions are now, the interne serving his time in any of the general hospitals has practically no opportunity whatever to familiarise himself with the diagnosis and treatment of pulmonary tuberculosis It is small wonder, therefore, that so large a proportion of the general practitioners fall far short in their diagnoses of pulmonary tuberculosis The present practice also fosters the erroneous belief in some miraculous virtue in climate in the treatment of tuberculosis, yet those familiar with the disease recognise that it is the proper use of fresh air which constitutes the valuable element in treatment at the various well known sanatoriums

In an effort to make better provision for the tuberculous among discharged soldiers, and at the same time to help bring about an improvement in our campaign against tuberculosis, Dr Hugh S Cumming, Surgeon General of the U S Public Health Service, has sent the following telegram to the American Medical Association, now in session in New Orleans, La —

"I desire to urge more active participation by the general practitioner and by general hospitals in the treatment of tuberculosis To insure earlier diagnoses properly train internes and other personnel popularise treatment in the home climate, provide additional facilities I earnestly indorse the resolution passed by the National Tuberculosis Association in 1916 recommending that general hospitals should admit tuberculous patients and provide separate wards for that purpose Sanatoriums and specialists in tuberculosis will always be needed and we should have more of them, but I believe that success in the antituberculosis campaign is largely dependent upon first convenient facilities for observation and prompt treatment of patients with open tuberculosis, and second, in a sharpened perception and higher degree of skill by which the family doctor will make early diagnoses or even forestall the development of clinical tuberculosis in the adult before a definite diagnosis is possible To provide adequate care for tuberculous ex Service men and others to protect infants from infection enlist the aid of the general practitioner, allay phthisiophobia, and improve home treatment of tuberculosis, the opening of general hospitals to this most common of all serious diseases will materially assist"

I write by direction of the Surgeon General, and am Sir, yours faithfully,

CHARLES BOLDUAN,
Chief Section of Public Health Education
Office of the Surgeon General Treasury Department, Bureau of the Public Health Service Washington May 4th 1920

*** The participation of the general practitioner in the treatment of tuberculosis whether domiciliary or institutional, is the principle which all medicine in this country supports —ED L

POSITION OF THE CITY BACTERIOLOGIST

To the Editor of THE LANCET

SIR,—The annotation in your issue of May 15th on the position of the city bacteriologist moves me to offer a few remarks With the bulk of it I am in complete agreement the proposed arrangement works very well, and the difficulty of specialising bacteriology is adequately met, as far as the student is concerned, by leaving the teaching of bacteriology to medical undergraduates in the hands of the professor of pathology But it is untrue and unfair to imply that pathological work in many university laboratories has in the past been "starved" Universities have had many claims to meet, and on the whole pathology has had its fair share, it may have been a Chittenden diet, which is stimulating, but it cannot be reasonably described as starvation And to say that "research can only be satisfactory when carried out in a well equipped laboratory with a qualified and adequately paid staff" is equally untrue and equally unfair both to the magnificent achievements of the past, and to the tolerable performances of the present The real necessaries are imagination, brains, and industry If the sentence I have quoted means only that research would get along better if it had more money it is a pity not to say so, exaggerated hyperbole is as much out of place in stating the claims of the pursuit of natural knowledge as it would be in the narration of its results You repeat also the now familiar plaint about the immense gains which would accrue to medicine if professors of pathology, and so forth, had "free access to the wards and the status of physicians" I do not know whether you have considered how such a plan would work in actual practice The objects in the wards to which access is wanted are sick people Someone has to be responsible for doing the best that can be done to make them better, and that someone has got to have undivided control over their treatment If pathologists are better at this kind of work than physicians and surgeons, they are even more remarkable people than I have thought them to be—and probably worse pathologists For from the point of view of the progress of pathology such an arrangement would be, avoiding hyperbole, quite a bad one Pathology is a biological science, and there is a deal of it which has little or no immediate connexion, at the moment, with sick people Turn over the pages of some of the great books in pathology—Cohnheim's Lectures, Barlow's General Pathology, the first volume of Adami, Bordet's Immunity It is not within the compass of an ordinary human mind to make itself fit to live with such problems as are there raised, and to be the wise physician that the sick person wants at the same time The great conceptions of chemistry have not often been born in steel or cement works, the great discoveries of pathology have seldom been made at the bedside There are indeed not many of them, there might have been more if less of the energy of pathologists had been put into its technical applications What medicine gains from pathology and what pathology gains from medicine—and both are very large—can properly be achieved by the encouragement and development of what we commonly call "clinical pathology"—i e, the application to practical medicine of those parts of pathology which are technically useful It is quite unnecessary to hamper the study of pathology on the one hand, or to hazard the well being of the sick on the other —I am, Sir, yours faithfully,

Radlett May 16th 1920 A E BOYCOTT

SPECIFICITY AND EVOLUTION IN DISEASE

To the Editor of THE LANCET

SIR,—In the retrospect contributed under the above title, Sir William Collins does good service in again raising the issue as to whether or no we have yet realised the importance of evolutionary processes in the causation of disease He concludes, however, with the question, "Is not the theory of specificity of disease swallowed up in the larger theory of evolution?" and there seems an implied suggestion that the theories are mutually antagonistic Is this really the case? In a consideration of the factors involved in the spread of bacterial infection,[1] I was recently led to suggest, on experimental and theoretical grounds, that a possible explanation of the epidemic spread of disease might be found in a progressive variation of the causative virus, itself determined by changes in its environment; and a tentative hypothesis was advanced with regard to the causes and character of such a variation.

---

[1] The Spread of Bacterial Infection, Goulstonian lectures 1919 THE LANCET 1919 ii p 1 et seq

In considering some of the possible deductions from such a theory, it was pointed out that—

> "It might, perhaps, be supposed that the acceptance of such a view as this would involve the belief that any bacterial parasite, given the requisite environmental conditions, might give rise to epidemic disease. Neither clinical nor bacteriological experience would, however, lend any support to such a view. ...... It would seem that we are dealing with a more or less specific capacity for variation, analogous to the acquired capacity for bringing about certain fermentations, which has been studied by Penfold and others. As the result of certain environmental changes the bacterial parasite will vary in a particular direction; but the ability to react in this way must be regarded as something inherent in the organism itself."

Thus an evolutionary hypothesis, in which especial emphasis is laid on changes in environment, does not exclude a belief in specificity, provided that this doctrine be not applied with an unintelligent rigidity. There is little evidence that we have fallen into error in believing that a given "disease" is caused by a specific organism, or sometimes by one or more of a definite group of organisms, and that in their absence the "disease" cannot occur. There seems reason, however, for thinking that we have not attributed sufficient importance to differences between various "strains" or "races" of a given bacterial species, or to the preponderating influence of environment on the evolution of those strains of the parasitic species which produce infection of the host. The future of preventive medicine would seem to be closely bound up with the acquirement of a fuller knowledge of the factors concerned in the production of such variations, and of the nature of the differences produced. An excellent example of the type of inquiry which will yield the data on which we must build is afforded by the admirable studies of Dr. A. Stanley Griffith on the types of *B. tuberculosis* isolated from various lesions in man.

The benefit that would most certainly accrue from the investigation of pathological problems on a wider and more comparative basis than is at present practised was pointed out by Sir Clifford Allbutt some months ago in a letter to the *Times*. If research and teaching could be established on the lines he indicates, there is little doubt that a decisive advance would be made along the path that will one day lead us to the conquest of infective disease.—I am, Sir, yours faithfully,

W. W. C. TOPLEY.

Institute of Pathology, Charing Cross Hospital, May 15th, 1920.

ANEURYSMAL VARIX IN THE NECK.

To the Editor of THE LANCET.

SIR,—A woman, aged 71, had a fall some years ago while cleaning a window. The frame broke and she fell backwards with frame and window on her. Nothing was noticed at the time in the neck, but she had glass removed from the face. Recently she developed an aneurysmal saccular swelling about the middle of the right transverse cervical artery, causing much pain and throbbing. The artery was tied by me near its origin on March 23rd last and the existence of a large expanded vena comes noted, which filled up with each beat of the artery. This sac has quite disappeared, but a fortnight ago aneurysmal swelling commenced in the inferior thyroid artery of the same side close to the clavicle and behind the sterno-mastoid muscle. As this aneurysm is so close to the origin of the artery to its parent trunk it would appear that further operation is impossible, especially in view of the patient's age. My friend, Mr. W. R. Williams, and I came to the conclusion that palliatives were now the only resource. The first part of the subclavian has, I believe, never been tied. If it were, what degree of collateral circulation would there be? I am writing this as I believe aneurysm of the thyroid axis and its branches are not common and aneurysmal varix very rare.

I am, Sir, yours faithfully,

May 17th, 1920. E. C. B. IBOTSON.

PROFESSIONAL SECRECY AND VENEREAL CLINICS.

To the Editor of THE LANCET.

SIR,—As it must be most distasteful to the medical officers of venereal disease clinics to be compelled in the courts to reveal their patients' conditions, would not a simple procedure avoid the possibility of this? The name of the patient is of no consequence to the medical officer. I should suggest that the registrar, or clerk, or nurse at the clinic receive directions to give to each patient a number, which would be written on their attendance cards previous to their seeing the medical officer; which number would on no account be changed during the whole course of treatment. Then the question of the name of the patient need not arise in the clinic at all and the position of both medical officer and patient would be more satisfactory; and there would be less hesitancy on the patient's part of availing himself or herself of the help held out by the Ministry of Health. I am, Sir, yours faithfully,

Dover, May 15th, 1920. F. A. OSBORN.

⁂ The plan has been suggested by others. The course of public and individual justice may make it necessary that the venereal state of a particular person at a particular time should be medically certified.—ED. L.

THE CULTIVATION OF THE MENINGOCOCCUS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of March 27th Dr. William A. Muir, in a letter bearing this title, commented upon my article on the Univalent Serum Treatment of Cerebro-spinal Fever which appeared in your issue of March 13th. Since I do not have the opportunity of seeing many cases of cerebro-spinal fever at present, I determined that I would not reply until I had treated at least another case. I have now done so. It confirms in all essential particulars the points made in my article.

Regarding the cultivation of the meningococcus, I have again been able to obtain a sufficient growth of the meningococcus on ordinary "coagulated blood serum" slopes within 20 hours of inoculation of the tubes. This was done both during the primary attack and during a relapse which occurred about three weeks after the primary attack had subsided. The growth was in each case sufficient for the purpose of carrying out the test for type by the microscopic method. It may be well to state that in each case about 1 c.cm. of cerebro-spinal fluid was allowed to run directly from the lumbar-puncture needle into the warmed culture-tubes, and the tubes were incubated within ten minutes. In control-tubes inoculated with only a few loopfuls of the fluid no growth occurred. In connexion with the relapse above quoted, direct microscopic examination of the fluid showed numerous pus cells, but no organisms, and yet, in culture, about a dozen colonies were available the next morning (20 hours).

Regarding agglutination, I again found the microscopic method to be sufficient to establish the diagnosis of Type I. of the disease. The only difference from my previous case was that the positive result was rather longer in appearing (six hours), and was very marked indeed in 24 hours. Comparatively, any tendency to agglutination which occurred with the other sera (and that affected Type II. only) was absolutely negligible. Any ordinary observer would have had no difficulty in pointing to Type I. as the reacting serum. I have no doubt that the macroscopic method is more accurate and more reliable. But here it is not necessary to determine the end-point of agglutination capacity of a serum, but merely to determine, given four high-titre sera, which of them is the chief or only reacting one. If low dilutions are put up, this, in my experience, can be done; and the test is an easier and more familiar one to most workers in the small laboratories attached to fever hospitals.

Regarding the administration of the homologous serum I have not found the delay in diagnosing the type of the disease to be sufficient to put the method out of use. In practice I have found Type I. to be the common type occurring in this area, and each case I have seen has presented almost identical and distinguishing clinical features. In such circumstances I have since my first case given the homologous serum first and diagnosed the type afterwards (within 24 to 48 hours—not a serious delay in this type of case). The response to the homologous serum treatment has been nothing short of marvellous. I have, of course, no objection to the use of the pooled sera of Types I. and II. until the diagnosis is established, but I hold that it is better to give the direct treatment if possible.

It may be of interest to mention that I have been informed by Dr. A. T. MacConkey, of the Lister Institute, that the particular batch of Type I. serum I have used in these cases was the pooled sera of nine horses and was prepared in July, 1918, almost two years ago.

I am, Sir, yours faithfully,
H. STANLEY BANKS.

Motherwell, May 12th, 1920

THE CONTROL OF VENEREAL DISEASE: THE MISSION OF HOPE.

To the Editor of THE LANCET.

SIR,—May we, through your columns, make an earnest appeal for financial help in connexion with the opening of a new isolation home in London for the treatment of venereal disease? Amongst the 400–500 cases of unmarried mothers of the better class whom we receive every year in our maternity homes and hostels a considerable proportion are tainted to a greater or less degree. At the present time we are constantly confronted by the urgent need for isolation of these, as well as of a number of infants who are also infected. On the advice of the Ministry of Health a suitable house has been purchased in a healthy district of South London through the kind gift of an individual donor, and the London County Council have agreed to make a generous contribution to the cost of maintenance. So far as its size will permit all cases, both of mothers and children, will be isolated here, and will receive treatment in the out-patient departments of various metropolitan hospitals.

We are greatly handicapped, however, by shortness of funds for furniture and equipment with a view to the speedy opening of the home. The matter is really extremely urgent, and a sum of £500 is required immediately. We are anxious that the institution may do something to meet the menace of this terrible foe to the nation, and cordially invite the practical help of your readers to this end.

Yours faithfully,
G. H. HUBBARD, V.D.,
Chairman
JANET WALLIS,
Honorary Director

The Mission of Hope (Incorporated), 30, Denman street,
London Bridge, S E 1

THE RELATION OF GENERAL MEDICINE TO OPHTHALMOLOGY.

To the Editor of THE LANCET.

SIR,—Mr. C. Higgens, in his letter in your issue of May 1st, appears to have misunderstood the object of my paper, which was, as the title indicated, not primarily for the "help of the ophthalmic surgeon," as he states, but for the "advancement of ophthalmology" and the benefit of our patients. He opposes the appointment of ophthalmic physicians on the extraordinary ground that it would be of "greater assistance to medicine than to ophthalmology." Now, I ask, what higher object could ophthalmology have than to be of assistance to general medicine? Ophthalmology is not a science apart from general medicine and in competition with it. Surely it should be our highest aim to contribute to the advancement of medical science as a whole. On it we depend for most of our knowledge and our ultimate diagnosis and treatment, and I hold that we neglect our opportunities of repaying something of the debt we owe to general medicine by denying the physician the opportunity of the continuous investigation of those obscure cases of disease in which the eye symptoms predominate and are the chief evidence of constitutional disease. By the limitations of our training and practice we are incapable of carrying out these investigations ourselves, and we refuse to the physician the opportunity which can only be obtained in our ophthalmic hospitals.

I am, Sir, yours faithfully,
RAYNER D. BATTEN.

Wimpole-street, W., May 17th, 1920

PROPOSED DEMOLITION OF CITY CHURCHES.

To the Editor of THE LANCET.

SIR,—If the proposed demolition of certain City churches is carried out, memorials in them to the following physicians and surgeons will disappear:—

All Hallow's, Lombard-street.—Dr. Edward Tyson, F.R.C.P., F.R.S., the "Carus" of Garth's "Dispensary."

St. Botolph, Aldersgate.—Two distinguished medical men are buried here, and their memory perpetuated upon their monuments: (1) Sir John Micklethwaite, surgeon to Charles II.; (2) Dr. Francis Bernard, physician to James II. and to St. Bartholomew's Hospital.

St. Dunstan's-in-the-West contains a tablet with a long Latin inscription to a foreign practitioner, Albert Otho Faber, who died in 1684, and who was upon the medical staff of Charles II.

St. Vedast, Foster-lane.—Sir Thomas Browne, author of the "Religio Medici," was baptised there.

I am, Sir, yours faithfully,
S. D. CLIPPINGDALE.

Holland Park-avenue, May 17th, 1920

The Services.

R.A.M.C. COMMISSIONS

THE War Office announces that a limited number of commissions in the Regular Royal Army Medical Corps will be given at an early date to officers who are at present serving in the army or who have held commissioned rank during the war. Intending candidates, who will be required to fulfil the undermentioned conditions, should write for forms of application and further particulars to the Secretary, War Office (A.M.D. 1), Cornwall House, Stamford street, London, S E 1 Officers who are still serving should submit their applications through the usual official channels.

Following are the conditions of service:—1. Candidates must be registered under the Medical Acts now in force in the United Kingdom. 2. Be under twenty-nine (29) years of age. Previous commissioned service, if as a medical officer of the Royal Army Medical Corps, will count towards seniority promotion and retired pay. Commissioned service other than as a medical officer will count only towards retired pay. The period of any such service may be deducted from an applicant's age if this is over twenty-eight (28) years. 3. Be pronounced fit for general service by a military medical board.

The rates of pay are as laid down in Army Order 324, an extract from which is appended.

Army Medical Service	Per day		
	£	*s*	*d*
Major General	4	10	0
Colonel	3	5	0
Lieutenant Colonel	2	10	0
" after 20 years' total service	2	12	6
" " 25 " "	2	15	0
Major	1	15	0
" after 15 years' total service	2	0	0
Captain	1	5	0
" after 5 years' total service	1	7	6
" " 10 " "	1	10	0
Captain, holding higher rank by Brevet, in addition	0	2	0
Lieutenant	1	0	0

The rates of allowances, gratuity, retired pay, &c., will be communicated to intending candidates.

ROYAL NAVAL MEDICAL SERVICE.

Surgeon Lieutenant-Commanders to be Surgeon Commanders: A. T. Rivers, C. J. Aveling, J. M Hayes, P. B Egan, F. H Stephens, S. Bradbury, K. H. Hole, G F. Syms

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. F. S. Walker retires on retired pay

Lieutenant-Colonels and Brevet Colonels relinquishing the acting rank of Colonel: J. C. Connor, J. A. Hartigan.

Major H. H. J. Fawcett, Temp. Major W. E Home, Temp. Capts. J. R. C. Greenlees, A. J. Blake relinquish the acting rank of Lieutenant-Colonel.

Major T. E. Harty to be acting Lieutenant-Colonel.

Major P. J. Marett to be temporary Lieutenant Colonel whilst specially employed.

Capts. S. Fenwick, T. J. Hallinan, Temp. Capts N. A. A. Hughes, C. C. Forsyth, J. E. Thompson, and C. R. B. Von Braun relinquish the acting rank of Major.

Capts. P. J. Ryan and E. A. Strachan to be acting Majors.

Capt. J. J. Molyneaux is placed on the half pay list on account of ill-health.

T. W. Mason, late temporary Captain, and J. P. Bonfield, late Captain, Can. A.M.C., to be temporary Captains.

Officers relinquishing their commissions:—Temp. Major R. H. Bremridge (retains the rank of Major). Temp. Capt. F. R. Brown (granted the rank of Major). Temporary Captains retaining the rank of Captain: G. W. Ronaldson, F. B. Macdonald, F. B. Pinniger, T. S. Allen, T. E. Banister, E. L. Hopkins, P. S. Blaker, R. C. T. Evans, W. Fleming, R. W. D. Hewson, J. A. Ireland, J. A. Gilfillan, H. M. Drake, C. G. Whorlow, H. H. McClelland, P. C. Davie, G. V. Fiddian, T. Craig, R. Gellatly, J. P. Grainger, E. H. Dendy, C. R. B. Eyre, J. W. Steel, H. Daw, H. A. Lane, W. A. McLeod, J. W. Riddoch, C. K. T. Hewson, A. J. Beattie, T. Perrin.

Oversea Forces: South African Medical Corps.

H. Wolff to be temporary Captain.

The undermentioned relinquish their temporary commissions on account of ill-health:—Lieutenant-Colonels retaining the rank of Lieutenant-Colonel: P. S. Clark, R. L. Girdwood. Major W. Gilbert (granted the rank of Lieutenant-Colonel). Majors retaining the rank of Major: J. Hunter, R. C. M. Hoare, F. S. Jones, F. Pershouse, P. St. J. Wilkinson. Captains retaining the rank of Captain: A. P. M. Anderson, C. J. Battle, C. P. Bligh-Wall, T. L. Blackburn, I. J. Block, H. J. Brady, A. H. de W. Budler, T. P. Dowley, J. Duncan, H. Fox, C. Grant, A. L. Gurney, E. Hill, T. J. Howell, E. W. Ingle, A. M. B. Jassinowsky, A. H. Lawrence, R. L. Lloyd, J. J. Louwrens, G. M. MacKay, P. E. Millard, J. A. Mulvany, J. D. Murdoch, W. Paisley, P. Parnell, W. A. Rail, J. Rauch, C. D. Roberts, J. Rose, C. L. Seccombe, S. F. Silberbauer, St. J. Stanwell, L. V. Tebbs, J. C. Venniker, J. R. Whyte, H. Wolff. Captains and Dental Surgeons retaining the rank of Captain: J. Figdor, S. M. Macpherson, C. B. Woolf.

SPECIAL RESERVE OF OFFICERS.

Capt. T. G. Fleming relinquishes the acting rank of Major.

Capts. F. E. Feilden and J. I. Watson relinquish their commissions and retain the rank of Captain.

TERRITORIAL FORCE.

Lieut.-Col. (Bt. Col.) W. Howorth, T.D., resigns his commission and retains his rank, with permission to wear the prescribed uniform.

Major A. Carless resigns his commission and is granted the rank of Colonel.

Major (Bt. Lt.-Col.) (acting Col.) H. A. Leebody relinquishes the acting rank of Colonel on vacating the appointment of Assistant Director of Medical Services.

Capt. (Bt. Major) C. W. Rowntree resigns his commission and retains the rank of Captain and Brevet Major.

Capt. R. Burgess resigns his commission and is granted the rank of Lieutenant-Colonel.

Capts. C. C. Philip, T. P. Edwards, and C. Jephcott resign their commissions and retain the rank of Captain.

Major Sir A. W. Mayo-Robson, 3rd London General Hospital, and Major A. Carless, 4th London General Hospital, are restored to the establishment on ceasing to hold temporary commissions in the Army Medical Service.

Sanitary Service: Capt. L. R. Tosswill to be Major.

TERRITORIAL FORCE RESERVE.

Lieut.-Col. (Bt. Col.) H. W. Webber resigns his commission and retains his rank.

ROYAL AIR FORCE.

Capts. H. J. Leviseur and W. G. Robertson are transferred to the unemployed list.

INDIAN MEDICAL SERVICE.

Lieut. P. J. Walsh (since deceased) to be Captain.

The King has approved of the retirement of Major F. N. White, C.I.E.

ROTUNDA HOSPITAL, DUBLIN, VERSUS THE INCOME-TAX COMMISSIONERS.—Judgment has now been given in the House of Lords in a lawsuit between the Commissioners of Inland Revenue and the governors of the Rotunda Hospital. The hospital has had since its foundation, as part of the hospital buildings, a suite of entertainment rooms from the rent or hirings of which it has drawn a substantial income. For many years in the early history of the hospital the rooms were the fashionable assembly rooms of Dublin, and until some 20 years ago they were commonly used for balls and concerts of high standard. The ingenious Bartholomew Mosse, who founded the hospital, had looked to this source for an important part of the income of his great foundation. A year or two ago the income-tax authorities demanded that the governors should pay income-tax under Schedule D on earnings of the entertainment rooms. The claim was resisted, and the Irish courts in several judgments supported the position taken by the governors of the hospital. The House of Lords has now reversed these decisions, and has given judgment in favour of the income-tax authorities.

Parliamentary Intelligence.

HOUSE OF COMMONS.

TUESDAY, MAY 11TH.

Back Pay in the Royal Air Force Medical Service.

Mr. DENNIS HERBERT asked the Secretary for War and Air if he was aware that great hardship and much discontent was being caused among members of the medical service of the Royal Air Force by the delay in payment of back pay, now many months overdue; and if he would take steps to see that these overdue payments should be made at once.—Mr. CHURCHILL replied: The arrangements for remustering Royal Air Force medical personnel to the new rates of pay have been under preparation for some time and the necessary order was issued last week.

Vaccination Statistics.

Mr. WILLIAM THORNE asked the Minister of Health whether, during the past 10 years, fewer children had been vaccinated in England and Wales than in any previous decade of the statistical history of vaccination; whether, during the same 10 years, there had been fewer small-pox deaths recorded than in any previous decade; and, if so, whether he would give instructions to his department to publish them widely so that the misapprehensions of the position, which were widespread in official medical circles, might be removed.—Dr. ADDISON replied: The answer to the first two parts of the question is in the affirmative. The statistics as regards vaccination and small-pox have been published year by year in the reports of the Local Government Board, and I am not aware of any misapprehension of the position in official medical circles. But I may point out that a consideration of these statistics without regard to other relevant facts may result in a misapprehension of the protective value of vaccination against small-pox. This matter was referred to recently in the Forty-eighth Annual Report of the Local Government Board (Medical Supplement), 1918–19, Cmd. 462.

Medical Students retained in Mesopotamia.

Major GLYN asked the Secretary for War and Air whether War Office Telegram, No. 39,313 of March 19th, 1920, Mob. 2, stated that all non-regular officers were liable to retention beyond April 30th, 1920, irrespective as to whether they did or did not volunteer service; whether in the case of medical students especially whose services were being retained in Mesopotamia, this War Office instruction was a reversal of the policy laid down in a speech delivered by him on Feb. 23rd, in which it was stated that all such officers would be demobilised by the end of April; and whether in these circumstances he would give special consideration to medical students who were desirous of immediately returning home to continue their studies enabling them to qualify for the medical profession.—Mr. CHURCHILL replied: The telegram mentioned stated that non-regular officers may be retained beyond April 30th, 1920, provided that the following conditions were fulfilled: (*a*) They fill an appointment within an authorised establishment; (*b*) no regular officers are available to replace them; (*c*) it is quite impossible to dispense with their services without relief. The telegram also stated that as soon as regular officers are available to replace them all non-regular officers must be demobilised. In my speech on Feb. 23rd last I referred only to the release of conscripts. I would remind the honourable and gallant Member that officers hold their commissions during His Majesty's pleasure. At the same time, every effort has been, and is being, made to replace temporary officers, and I regret that I am unable to take any exceptional action in the case of medical students.

WEDNESDAY, MAY 12TH.

English Medical Officers in India.

Sir W. JOYNSON-HICKS asked the Secretary for India if he could state the number of officers of the Indian Medical Service, native and European, in 1914 and 1919; how many of each race were gazetted in 1919; and what steps he was taking to make the service attractive to English doctors.—Mr. MONTAGU replied: In 1914 the number of officers in the Indian Medical Service was 706 Europeans and 63 Indians. In December, 1919, excluding officers holding temporary commissions, there were 650 Europeans and 80 Indians. During 1919 25 Europeans and 21 Indians were appointed to permanent commissions. In amplification of improvements already sanctioned, I hope to announce at an early date increased rates of pay and pension for the Indian Medical Service. I also recognise that it is essential to improve the facilities for leave and study, but no decision on these points can be effective until recruitment has brought the service nearer to its normal strength.—Sir W. JOYNSON-HICKS: If I put a question in a month's time, will the right honourable gentleman say if he hopes to be able to give the increases and the other arrangements for improving the service?—Mr MONTAGU Yes, I hope so, and if my honourable friend will permit me as soon as a decision has been reached, which, I hope, will be only a matter of a few weeks, then I will let him know

Inter departmental Committee on Tuberculous Soldiers

Major BARKER asked the Minister of Health whether he had yet considered the proposal of the Inter departmental Committee on Tuberculous Soldiers, and whether he could state which of these suggestions was being adopted —Dr ADDISON replied The answer to the first part of the question is in the affirmative The capital grant in aid of the provision of additional sanatorium and hospital accommodation for tuberculosis has been increased to £180 per bed and considerable extensions of the existing accommodation are being made Facilities for the training in suitable occupations of ex Service men suffering from tuberculosis are in course of being provided at existing sanatoriums at an estimated cost of £250,000, and a scheme for the provision of village settlements for these men and their families has been worked out, and is now under consideration by the departments concerned

Maternity and Child Welfare

Mr WATERSON asked the Minister of Health if he was aware that many municipal authorities found it impossible to develop the work of maternity and child welfare as it ought to be developed because of the heavy financial burden it entailed, and, under such circumstances, could he make any recommendations to the Government for financial assistance to carry out a national obligation, and from which the State would benefit —Dr ADDISON replied The Government already distribute through my department a grant of half the expenditure of local authorities and voluntary agencies on maternity and child welfare

Hospital Transport in Egypt

Mr RUPERT GWYNNE asked the Secretary for War whether he was aware that a number of officers and men medically boarded for transfer to the United Kingdom after several years' service abroad were being retained in Egypt because no hospital ship was available to transport them, and that owing to the hot weather prevailing in Egypt at the present time their health was suffering and some of them might die in consequence of the delay, whether, while means could not be found to transport our British sick to the United Kingdom, a hospital ship was being used to repatriate Turkish prisoners from Egypt to Turkey, and other hospital ships to transport Russian refugees, and whether he would see that priority was given to our men suffering from the climate, and that arrangements were made for their immediate removal —Sir A WILLIAMSON (Financial Secretary to the War Office) replied No invalids have been held back in Egypt owing to a hospital ship not being available A hospital ship is allotted permanently for the evacuation to the United Kingdom of invalids from the Mediterranean garrisons, and is dispatched to the United Kingdom whenever the number of invalids warrants a sailing This ship has been used for the conveyance of sick Turkish prisoners of war from Egypt to Turkey between its voyages to the United Kingdom, but I am advised that it has only been employed in this manner when the number of British invalids for transportation to the United Kingdom did not warrant its immediate return to the United Kingdom, and that its use on this service has in no way delayed the evacuation of British invalids —Mr GWYNNE Is the right honourable gentleman aware that at present there are men urgently waiting to come home, and will he give orders for a ship to bring these men home at once?—Sir A WILLIAMSON I do not think that can be possible Ships can only bring them home when there are enough men to form a shipload We cannot send a ship for 20 or 30 men —Mr GWYNNE Does the right honourable gentleman mean that men who have served four or five years should be left out there to die rather than bring them back home?—Sir A WILLIAMSON No Sir, that would be quite an incorrect representation of the case A ship is sent whenever there are enough men to bring home The intervals are not so long as the honourable Member suggests —Mr GWYNNE How many dying men are enough to justify sending a ship? —No answer was given —Earl WINTERTON Is the right honourable gentleman aware that there are a large number of passengers who are coming home on these ships now who could be taken off and these invalids put on board? Is he aware that men out in Egypt who have been ordered to be sent home two or three years ago have not yet been sent home?—Sir A WILLIAMSON I am not aware that passengers are brought in hospital ships I think that the hospital ships are confined to hospital purposes If the suggestion is that that is not so I will inquire into the matter —Mr GWYNNE Will the right honourable gentleman inquire into the cases of the men that are out there now?—Sir A WILLIAMSON Yes

Emergency Coal-supplies in Cases of Illness

Mr JEPHCOTT asked the President of the Board of Trade whether he was aware that recently in one family in Ashton under Lyne three children died in the course of a week after suffering from measles, and that it was believed the deaths were partly attributable to lack of warmth through the shortage of coal, if he had any information that equally serious results were occasionally occurring throughout the country, and whether a more abundant distribution of household coal could be rendered possible by reduced exports or other means —Mr BRIDGEMAN (Parliamentary Secretary to the Board of Trade) replied I have no information which supports the suggestion that deaths in this country have been directly caused by shortage of coal, but it would be a matter for great regret if such shortage had been a contributory cause It is a rule that any person who can obtain a medical certificate that coal is needed in a case of illness should be entitled to obtain from a merchant a supply of emergency coal forthwith As I have already informed the House on several previous occasions it has been the policy of the Government to ensure home supplies before allowing export of coal

THURSDAY, MAY 13TH

War Gratuity to Nursing Sisters

Captain THORPE asked the Secretary of State whether there was any reason why the nursing sisters employed at the Nell Lane Military Hospital, West Didsbury, Manchester, should not be paid their war gratuities, and whether he would authorise the immediate payment of gratuities to all nurses who were duly qualified to receive them —Sir A WILLIAMSON replied The Guardians of Manchester Union by whom the nurses in question were employed, have been invited to pay the gratuities due on behalf of the War Department but prefer not to do so Steps are being taken to make payment direct

FRIDAY, MAY 14TH

National Health Insurance Bill Removal from the Panel

The House considered the National Health Insurance Bill as amended in Standing Committee

Captain ELLIOT moved a new clause providing that —

> (1) Any medical practitioner aggrieved by a decision of the Minister or of any special body through which the powers and duties of the Minister, under Section 15 Subsection (2) (b), of the Act of 1911, are exercised, to remove his name from any list of medical practitioners may appeal against the decision to the High Court within the time and in the manner and on the conditions directed by the rules of court (2) The cost of any such appeal shall be in the discretion of the court, and no appeal shall be allowed from any order or decision of the court in any such appeal

He said that this was a right granted to medical practitioners in the 1911 Act which was apparently being taken away from them under this Act If they were struck off the panel they had a right of appeal under Subsection 15 (b) of the 1911 Act All the right of appeal they had now was to the Minister of Health If a medical practitioner was struck off the panel he was debarred from the treatment of what was already a majority of the population of the kingdom, and what would, if the dependents were brought within the scheme of the Act, become an overwhelming majority of the people The medical profession did not consider it was fair that the bureaucracy should have this tremendous power over a medical practitioner, on the ground first that it would lead to a stereotyping of medical practice Nobody would risk embarking on some individual line of treatment if he knew that any failure of that treatment would be brought before a committee of what were after all his trade competitors In this case the bureaucracy was extending its power over the ordinary surgeon A man who had the right to enrol his name on the panel of doctors should not have his name removed without at least a chance to appeal to the courts of law —Lieutenant Colonel FREMANTLE seconded the new clause He said that there was a tendency for certain members of the profession to say, "We will not practise under these conditions We will have nothing to do with this panel practice" That was a bad condition for any Government service to get into He had a high opinion of his profession and of the Minister of Health who was the judge in this matter, but thought it was wrong that medical men should be judged in a matter like this by such a court as was suggested —Dr ADDISON said the Bill did not extend the power of the bureaucracy —Captain ELLIOT said that the Minister was a new Minister of the Crown, and here was a new bureaucracy —Dr ADDISON said that there was no word in the Bill at all which related to the conditions of the removal of the medical man from the panel The statement therefore that there was in this Bill an extension of the power of the bureaucracy was inaccurate *in toto* When a complaint was made under the original Act if a medical man was to be removed from the panel it had to be proved that he was doing something which was prejudicial to the efficiency of the service, and it had to be a very grave matter. In the next place, the case had to go before the Finance Committee, which was a lay body, not a body of jealous fellow medical men.—Colonel FREMANTLE: Are these words true, "This will apply only after an inquiry by his own professional brethren in the first place"?—Dr. ADDISON said that before the Insurance Committee stated their case they referred it to the Medical Committee to see if there was a case to be stated. But the Medical Committee did not judge the matter in any way at all. If there was a case at all it went to a tribunal set up in the original Act, consisting of two medical men who were experts not in the man's own area, and presided over by a barrister or solicitor. So that the jealous fellow practitioner did not appear. That body now reported to the Ministry of Health instead of to the Insurance Commissioners, who had now been absorbed in the new Ministry. There was nothing to compel a medical man to come off the panel. But Parliament never intended, he was sure, that there should be created a statutory vested interest. He had been Minister of Health for more than a year and had never had a single case come up to him yet. A case had to be very grave before it reached the Minister at all. This was a claim which had been practically condemned, and, if adopted, it would be copied in every other department, and would be most prejudicial to the interests of the public service. The medical men knew that they were very fairly treated indeed, and there was every facility for their case being inquired into.—Dr. MURRAY supported the amendment.—Major BARNES thought that the right honourable gentleman might set a good example to the rest of the Government by yielding the point.—Mr. ROBERTS thought that members of the medical profession were quite capable of looking after themselves and safeguarding themselves against injustice. As no power was now being withheld, and as no injustice as far as they could ascertain had yet arisen, a dangerous precedent would be set up if this amendment were passed.—Major FARQUHARSON said if it should happen that a trade competitor were serving upon the Committee when a doctor was appearing to answer a charge, he had sufficient faith in his profession to feel sure that such a person would withdraw from the inquiry. If the Minister in the exercise of his Ministerial capacity ever did a thing or caused a condition to arise over which a doctor would be "aggrieved" in the technical sense of the 1911 Act, the proper place to deal with him was in that House.—Captain ELLIOT said that it was impossible to legislate under these conditions—it was now after 1 o'clock in the morning—and he therefore withdrew his amendment.—After further discussion the proposed new clause was negatived.

Discontinuance of Sanatorium Benefit.

Lieutenant Commander KENWORTHY moved to omit Clause 4 of the Bill which provides for the discontinuance of the administration of sanatorium benefit under the National Health Insurance Act, except in Ireland.—Dr. ADDISON, in opposing the amendment, explained that cases of tuberculosis were in future to be dealt with by one authority and claimed that the new arrangements would benefit working men. They desired that the treatment of tuberculosis should be extended where necessary. The whole scheme of which this was designed to be a part was to secure that one authority was competent to deal with all stages of tuberculosis. They only proposed to transfer the service from one set of people to another, but they proposed that the authorities should have added powers and added funds to perform this service for the benefit of the insured person.—Mr. MYERS thought that one of the most tragic features of the public health administration of the country was the complete inability of the medical profession of this country to effect an early diagnosis of tuberculosis, or at least their failure to disclose the fact that they had made the discovery. A year or two ago he attended an important conference in London addressed by Professor Beraneck, of Neuchâtel, a tuberculosis specialist from Berlin, and Sir Robert Philip, of Edinburgh. These medical experts set forth the fact that no medical man ought to administer tuberculin unless he was fully qualified in its elements. He would encourage early diagnosis of the disease on the part of the medical man, and as soon as diagnosis had been effected he would take the treatment out of the hands of the ordinary panel doctor absolutely and put it into the hands of a specific expert authority.—Dr. MURRAY said he did not agree with the aspersions cast upon the general practitioner. He would much prefer to be in the hands of the average general practitioner if he suffered from tuberculosis than in those of the best so-called expert in the country.—The amendment was negatived.

Dr. ADDISON moved to insert a new subsection to provide that the medical men on the panel should be authorised to ask the Insurance Committees to allow up to 2*d*. instead of 1*d*. per insured person to be allotted towards the administrative expenses of committees elected by medical practitioners and persons supplying drugs and medicines. It was their money, and it came out of their funds and not out of the general funds of the Act.—The amendment was agreed to.

The report stage of the Bill was concluded, and the Bill was read a third time.

Blind Persons Bill.

Dr. ADDISON, in moving the second reading of the Blind Persons Bill, said that the Bill was the result of a pledge given to the House recently during the discussion on a private Member's Bill on the same subject. In consequence of the very useful work of the Advisory Committee on the Blind a complete survey had been made of existing agencies for dealing with the blind, gaps in the present facilities had been discovered, and it had been possible to frame this Bill on sound lines. Steps had been taken to increase the preventive services against blindness, and Mr. G. Barnes had undertaken to preside over an important inquiry in regard to that matter. It was known that blindness in infancy was associated in a large degree with one form of venereal disease. Apart from preventive services, there was need that facilities should be provided for blind persons to learn some trade in order to earn a livelihood, and the Bill would enable local authorities to provide and maintain or to contribute towards the provision and maintenance of workshops, hostels, homes, or other places for the reception of blind persons within or without their area, and to combine to make further arrangements for promoting the welfare of the blind. The amount of the Government grant towards the expenses would be increased to 50 per cent. Provision would also be made by the measure that those persons who were so blind as to be unable to perform any work, and were 50 years of age, should be entitled to receive the pension to which, in ordinary circumstances, they would become entitled under the Old Age Pensions Act on reaching the age of 70 years. The Bill would render the War Charities Act, 1916, applicable to charities for the blind, and make it necessary that those charities should be registered and approved.—Mr. NEIL MACLEAN, speaking for the Labour Party, did not regard the Bill as adequate to meet the circumstances of the blind men. If the sympathies of the House were to be translated into benefits for blind people the Bill must be compulsory and not permissive in character. The Labour Party would not retard the second reading of the Bill, but when the Committee stage was reached they would do their best to remodel and strengthen it.—The Bill was read a second time.

MONDAY, MAY 17TH.

British-made Morphia.

Mr. GILBERT asked the President of the Board of Trade if he would state to which countries British-made morphia was exported during the year 1919, the amount and value of the morphia so exported to each country, what precautions were taken to secure the restriction of such morphia to medical or legitimate purposes; how many factories for morphia there were in Great Britain; and whether they were controlled and supervised in accordance with the provisions of the International Opium Convention of 1912.—Sir ROBERT HORNE replied: I am sending the honourable Member a statement of the recorded exports of morphia which will be printed in the official report, but I regret that those figures do not include exports through the post, particulars of which are not available. Licences are granted by the Board of Trade on the basis of the estimated legitimate requirements of the country of destination, and an arrangement is already in force in regard to certain destinations, and will, I hope, be extended to others—under which an application for a licence must be accompanied by a certificate from the appropriate Government authority in the country of destination that the drug is required exclusively for legitimate medicinal or scientific purposes, and will not be re-exported. I am aware of only three factories in Great Britain producing morphia. When the Dangerous Drugs Bill at present before the House is passed into law control over such factories will be exercised in accordance with the provisions of the Opium Convention.—Sir J. D. REES: Does the Government intend or endeavour to control morphia all over the world?—Sir R. HORNE: We cannot hope to accomplish such a vast undertaking.—Sir J. D. REES: But does not my right honourable friend's answer imply that we are to control the morphia from British factories in all parts of the world?—Sir R. HORNE: From British factories, certainly.

Vaccination and Small-pox.

Mr. WATERSON asked the Minister of Health if, in view of the opinion expressed by Dr. R. J. Reece on page 92 of the Medical Supplement of the Forty-eighth Annual Report of the Local Government Board that at any isolation hospital which was likely to receive small-pox cases the staff should always be protected beforehand by efficient revaccination, he would state what constituted an efficient revaccination, and how long it might be presumed to remain efficient; and whether, and if so what, steps had been taken by the Ministry of Health to inform those in charge of isolation hospitals as to the views of the Ministry on the subject.—Dr. Addison replied: I am advised that efficient revaccination should result in the appearance of either vesicles, normal or modified, or papules surrounded by areolæ. If no such result is obtained, and some years have elapsed since the last successful vaccination or revaccination, the operation should be repeated if the person is especially liable to exposure to small-pox infection. A successful revaccination ordinarily protects those exposed to infection for many years against the occurrence of severe or fatal small-pox, and for a shorter period against the occurrence of a mild or modified attack. I am, however, advised that persons whose duties at isolation hospitals render them especially liable to exposure to small-pox infection should renew their protection by vaccination at least every ten years. These views are in accordance with generally accepted medical opinion, and I scarcely think it necessary to communicate them to those in charge of isolation hospitals.

Medical Services in the Navy.

The House went into Committee on the Navy Estimates, Sir E. Cornwall in the chair.

On a vote of £677,300 for the expenses of medical services, including the cost of medical establishments at home and abroad, Sir D. Maclean asked for further explanation. They ought to be told why, while the numbers of the navy generally had gone down, the medical service showed no corresponding reduction, either in numbers or cost.—Sir J. Craig said it was impossible suddenly to drop from war conditions to peace conditions without going through a transition stage. He admitted, however, that something might be done to make the estimate a little clearer and he would promise to meet Sir Donald Maclean's wishes in regard to that.—Sir D. Maclean urged that the House should be given further information before the Report Stage.—Sir J. Craig said that this vote covered home and abroad shore services which were normally the same and not affected by the large reduction in the navy. He would, however, be glad to give any further information that was possible.—The vote was agreed to.

Medical News.

Royal College of Physicians of London.—An extraordinary Comitia of the Royal College of Physicians of London was held on May 13th, Sir Norman Moore, the President, being in the chair.—On the nomination of the President Dr. James Taylor was appointed to represent the College on a committee being formed by the Minister of Health to investigate the causes of blindness and defective vision. The Members elected to the Fellowship at the Comitia held on April 29th (see THE LANCET, May 8th) were admitted. Diplomas in Public Health and Diplomas in Tropical Medicine and Hygiene were granted, jointly with the Royal College of Surgeons, to candidates whose names will be found in the pass-list given below.—The President then dissolved the Comitia.

Royal College of Surgeons of England.—An ordinary meeting of the Council was held on May 13th, Sir George Makins, the President, being in the chair.—Professor Alexis Thomson was introduced, and after signing the by-laws and making the required declaration was admitted a Fellow of the College.—It was resolved to issue diplomas of Membership to 70 successful candidates.—In accordance with a report from the Court of Examiners it was resolved that the Council agreed with the Anatomical Society of Great Britain and Ireland in deciding not to depart from the old nomenclature for use in anatomical text-books and by medical men in general.—It was resolved to grant jointly with the Royal College of Physicians of London Diplomas in Public Health to nine successful candidates, and Diplomas in Tropical Medicine and Hygiene to 13 successful candidates.—The President reported that a letter had been received from the Lord Weardale, Chairman of the Committee for the "Save the Children Fund" of 26, Golden-square, W. 1, soliciting the help of Fellows and Members of the College, and stating that under their "professional assistance" plan any contribution made through the College would be devoted exclusively to feeding and tending children whose parents are surgeons. The President regretted that there were no corporate funds available from which a contribution could be made, but took the opportunity of calling the attention of Fellows and Members of the College to the appeal.—The President reported that he had sent a telegram of congratulation to Dr. Logie, M.D. Edin., 1842, L.R.C.S. Edin., 1841, on the occasion of the hundredth anniversary of the date of his birth on May 11th.

Royal Colleges of Physicians of London and Surgeons of England.—At a meeting of Comitia of the Royal College of Physicians on April 29th and of the Council of the Royal College of Surgeons on May 13th diplomas of L.R.C.P. and M.R.C.S. were respectively conferred upon the following candidates who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the by-laws of each College:—

William Eric Hallamore Banks, Cambridge Univ. and St. Bart.'s Hosp.; William George Barnard, London Hosp.; Benjamin Faltas Behman, Univ. Coll. Hosp.; Julia Bell, Royal Free and St. Mary's Hosps.; Walter Bowler, Liverpool Univ.; Harold Currie Brayshaw, Edinburgh Univ; Osmond Hayman Brown, Charing Cross Hosp.; William Mark Brown, Guy's Hosp.; Kenneth Entwisle Bury, St. Thomas's Hosp.; John William Chadwick, Manchester Univ.; Isabel Martha Collier, Liverpool Univ.; John Joseph Philip de Chaumont, Charing Cross Hosp.; Purshottam Mulchand Desai, Bombay Univ. and London Hosp.; Kenneth Henry Doouss, St. Bart.'s Hosp.; Edward Ernest Elt, Charing Cross Hosp.; Roger Henry Emmett, Cambridge Univ. and St. George's Hosp.; Cecil Weldon Empey, London Hosp.; Gerald William Thomas Hunter Fleming, Durham and Charing Cross Hosp.; Louis Francois Regis Charles Laurent Folliet, Paris, Lyons, and Univ. Coll. Hosp.; Richard Kenrick Foulkes, King's Coll. Hosp.; Donald Goddard Garnett, Cambridge Univ. and St. Thomas's Hosp.; Arthur Christopher Vidal Gosset, Cambridge Univ. and St. Thomas's Hosp.; Arthur Edwards Gravelle, King's Coll. Hosp.; Egerton Charles Grey, Guy's Hosp.; Churchill Hector Gunasekara, Cambridge Univ. and Middlesex Hosp.; Edith May Hall, Royal Free Hosp.; Reginald Rowley Halsall, Manchester Univ.; Theodore Handel, King's Coll. Hosp.; Ranald Montagu Handfield-Jones, St. Mary's Hosp.; Tom Robert Ernest Hillier, Middlesex Hosp.; William Vincent Hughes, St. Mary's Hosp.; Donald Hunter, London Hosp.; Frank Carlton Jones, Manchester Univ.; Charles Ainger Kirton, Univ. Coll. Hosp.; Frans Hieronymus Kooy, Groningen Univ.; Wright Lambert, Middlesex Hosp.; George Valentine Chapman Last, Liverpool Univ.; William Alexander Low, St. Thomas's Hosp.; Ernest Lowe and Thomas Clyde McKenzie, Birmingham Univ.; Naguib Makar, St. Thomas's Hosp.; Margaret Ombler Meek, Cambridge Univ. and Charing Cross Hosp.; John Roderick Mitchell, Cambridge Univ. and St. Thomas's Hosp.; Bernard Molloy, Cork and Birmingham Univ.; George Geoffrey Newman, London Hosp.; Ahmed Othman, St. Thomas's Hosp.; Frederick Ferdinand Petersen, London Hosp.; Harold James Alexander Pollard, Cambridge Univ. and St. Bart's Hosp.; Henry Christoffers Powell, Charing Cross Hosp.; Reginald Francis Price, McGill Univ.; Joseph Proujansky, London Hosp.; Thomas Reed, Guy's Hosp.; Owen William Roberts, King's Coll. Hosp.; Isabella McDougall Robertson, Royal Free and St. George's Hosps.; Katherine Jane Shaw, Royal Free Hosp.; Ronald Cunliffe Shaw, Manchester Univ.; William Arthur Merrett Smart, London Hosp.; Harold Edward Smith, Sheffield Univ.; Arthur Twynham Spoor, Cambridge Univ. and St. Thomas's Hosp.; Edward Howard Strange, Cambridge Univ. and St. Bart's Hosp.; Canning Suffern, Cambridge Univ. and St. Thomas's Hosp.; Arthur Walford Taylor, St. Bart.'s Hosp.; James McWilliam Taylor, Western Univ.; Gifford Campion Thornton, Birmingham Univ.; Johan van Rooijen, Amsterdam Univ.; Robert Walter Warrick, Guy's Hosp.; Herbert Edward Williams, London Hosp.; Lucy Wills, Royal Free Hosp.; Joseph Marshall McCaldin Wright, Cambridge Univ. and King's College Hosp.; and Philip Richard Zinn, New York Univ. and Univ. Coll. Hosp.

Diplomas in Public Health were conferred upon the following nine candidates (including one woman) who have passed the requisite examinations:—

Eleanor Bourne, Sydney Univ. and Univ. Coll.; Monamy Aston Cornwall Buckell, Univ. Coll.; John Nairn Dobbie, Glasgow Univ. and Univ. Coll.; Harry Evans, Edinburgh Univ. and Univ. Coll.; George Alfred Duncan Harvey, Dublin and Royal Army Medical Coll.; George Dearden Jameson, Cambridge Univ. and St. Bart.'s Hosp.; William Simpson, St. Bart.'s Hosp.; James Garfit Wallis, London Hosp. and Haslar; and Graham Selby Wilson, Charing Cross Hosp. and Royal Army Medical Coll.

Diplomas in Tropical Medicine and Hygiene were also conferred upon the following 13 candidates from the London School of Tropical Medicine who have passed the requisite examinations:—

Mohamed Khalil Abdel-Khalik, John Scaife Armstrong, Carlo Basile, Alexander Kirkpatrick Cosgrave, Ernest Forrester-Paton, John Augustine Frendo, William Peat Hogg, Thomas Skene Keith, Alexander William Montgomery Harvey, Niels Nedergaard, Harold Edward Whittingham, Man Wong, and Edward Jenner Wood.

Royal College of Physicians of Edinburgh, Royal College of Surgeons of Edinburgh, and Royal Faculty of Physicians and Surgeons of Glasgow.—At a recent examination of the Board the following candidates, having passed the First and Second Examinations, were admitted Diplomates in Public Health:—

Maurice Exell Willcock, Stanley Honeyman, George King, Ian Campbell Mackay, Ralph Johnston Tait, Margaret Allison Alexander, Thomas Macmillan Anderson, Philip Clermont Livingston, James Whitson Kemp Bruce, Herbert Frederick Wilfrid Adams, Edward Fow Fisher, Jessie Alexander MacLaren, Thomas Pearson Herriot, Alexander Bremner, and Andrew Gray Carment.

The President of the French Republic has conferred the honour of Officer of the Legion of Honour on Professor Aldo Castellani, C.M.G., of the London School of Tropical Medicine, for his work on combined typhoid-paratyphoid and enteric-cholera vaccination, and other scientific investigations which have been found of utility to the Allied armies during the war.

University of London.—On May 19th, at a meeting of the Senate, Dr. Russell Wells, the Vice-Chancellor, presiding, it was reported that an offer had been received from the President of the Board of Education of a site for central buildings immediately behind the British Museum.—At the Albert Hall on the same day degrees were presented to a large number of graduates, and in the evening at the Guildhall the graduates dined together, Dr. Russell Wells presiding, the Lord Mayor of London coöperating with him in receiving the guests. Interesting speeches were made by the Lord Chancellor and the President of the Board of Education.

National Council for Combating Venereal Diseases: Appointment of Travelling Commissions.—The National Council has been invited to despatch two commissions under the ægis of the Colonial Office, one travelling east and the other travelling west, so that the benefit of recent experience gained in this country may be made available in our colonies and dependencies. The commissions will each consist of one lay and one medical member, the latter to give post-graduate courses to the local medical faculties under the auspices of the various Colonial Medical Services. The tour is to begin in September and to last from six to eight months. On the western tour the medical commissioner would be required to demonstrate the Wassermann technique; although desirable, this would not be absolutely necessary for the eastern voyage. In addition to more technical medical instruction he would be invited to give addresses to lay audiences. Travelling expenses and a small honorarium are offered. The final selection of medical commissioners has not been made. Names of applicants are now being considered by a special committee, and should be sent to the N.C.C.V.D., 80, Avenue Chambers, London, W.C. 1.

There are still a few vacancies for the post-graduate course to be held by Mr. K. M. Walker at St. Bartholomew's Hospital Clinic on the Diagnosis and Treatment of Venereal Diseases on Thursday afternoons at 5.30 P.M. Any medical practitioner wishing to attend should send his name to the Secretary, N.C.C.V.D., at above address.

Society for the Prevention of Venereal Disease: A Parliamentary Committee.—A deputation of this society, consisting of Lord Willoughby de Broke, Sir W. Arbuthnot Lane, Sir James Crichton-Browne, Mr. Athelstan Rendall, M.P., Mr. W. Wansey Bayly, Miss Norah March, Dr. Jane L. Hawthorne, Dr. A. Mearns Fraser, and Captain W. E. Elliot, M.P., laid the views of the society before some 50 Members of Parliament at the House of Commons on May 12th. After hearing the policy of the society set forth, the Members present resolved to form themselves into a Parliamentary Committee with the object of furthering the aims of the society, more particularly in endeavouring (*a*) to obtain the support, both official and financial, of the Ministry of Health for the society's work; and (*b*) to obtain the repeal of the clause in the Venereal Disease Act, 1917, which forbids a chemist to recommend to the public or to expose for sale approved disinfectants for the prevention of venereal disease.

Manchester Conference on Diseases of the Teeth.—A Congress on the Prevention of Diseases of the Teeth, promoted by the Food Education Society, was held in Manchester from May 13th to 15th to attack "the dental problem, which remains after ten years of the School Medical Service one of the most important, urgent, and difficult." The conference was opened by Sybil, Viscountess Rhondda. Sir William Milligan, who presided, said that the teeth of Jewish children were superior to those of Gentiles, and he suggested that differences of diet might be the cause of this. Professor Adami compared the teeth of people of this country unfavourably with those of Canada, and emphasised the need for such revision of the Dental Act of 1878 as would ensure that only fully qualified persons should be allowed to practise dentistry. He said that 10,000 additional qualified dentists were needed to care properly for the teeth of the country. Dr. Harry Campbell said that the state of our teeth, which were the worst of any nation's, should excite a feeling of shame and humiliation. At least nine-tenths of this dental disease was preventable. Mr. F. M. Holborn characterised pyorrhœa as the commonest disease in this country next to dental caries. Tooth-brushing as generally practised, especially if tooth powders and pastes—so much in use—were driven under the free margin of the gum tended to injure the gum at its junction with the teeth. Used in moderation a toothbrush was harmless, but it should be drawn from the gum towards the teeth to avoid forcing particles beneath the gum. Salt and soap were the safest cleansers. He commended the practice of certain African natives who used a small piece of thin wood to polish the teeth and remove adherent particles. The blind brushing of the teeth from side to side and up and down should be condemned. One speaker considered tolerance and indifference the cause of much disease. "We should make it understood that good teeth are necessary to good form." "Toothless gums are not natural even to age." According to Dr. J. Wheatley, "milk is an excellent food if taken with the proper precautions. If taken late at night without any other food it is the most dangerous food I know."

Medico-Legal Society.—A meeting will be held at 11, Chandos-street, London, W., on Friday, May 28th, at 8.30 P.M., when a paper will be read by Dr. T. H. G. Shore on "Sudden Deaths on Active Service."

Mr. G. Q. Roberts, M.A., secretary to St. Thomas's Hospital, will deliver a lecture on "Old London and the London Hospitals" at the hospital on Friday, May 28th, at 5.15 P.M. Applications for tickets should be made to the Secretary, League of Mercy, 29, Southampton-street, London, W.C. 2.

Royal Institution.—On Tuesday next (May 25th), at 3 o'clock, Major C. E. Inglis begins a course of two lectures at the Royal Institution on the Evolution of Large Bridge Construction; on Thursday (May 27th) Mr. William Archer delivers the first of two lectures on Dreams, with special reference to Psycho-analysis; and on Saturday (May 29th) Professor J. H. Jeans commences a course of two lectures on Recent Revolutions in Physical Science: (1) The Theory of Relativity; (2) the Theory of Quanta. The Friday evening discourse on May 28th will be delivered by Professor W. L. Bragg on Crystal Structure; and on June 4th by Sir Ronald Ross on Science and Poetry.

St. Marylebone General Dispensary: Post-graduate Course on Infant and Child Welfare.—A course of 12 practical demonstrations on the Management and Feeding of Infants and Young Children will be given by Dr. Eric Pritchard to qualified practitioners on Tuesdays and Thursdays at the St. Marylebone General Dispensary, commencing Tuesday, June 1st. Opportunities will be afforded to those attending this course of visiting the Nursery Training School, 1, Wellgarth-road, Golders Green, on Saturday afternoons. Further information and tickets for the course (2 guineas) may be obtained from the Secretary, 77, Welbeck-street, Cavendish-square, London, W. 1.

Post-Graduate Classes at Norwich.—The demonstrations organised during the spring by the honorary medical staff of the Norfolk and Norwich Hospital have been well attended and much appreciated by qualified medical men in the city and neighbourhood. It is proposed to continue the demonstrations during the coming autumn and winter.

Norwich Medico-Chirurgical Society.—A clinical meeting of this society was held at the Norfolk and Norwich Hospital on May 4th, when the following cases and specimens were shown:—Mr. A. J. Blaxland: (*a*) Malignant Papilloma of Appendix causing Intussusception removed from man aged 63 years; (*b*) Sarcoma of Uterus from a woman aged 55 years; (*c*) Right Lobe of Thyroid showing great Parenchymatous Enlargement removed from a youth aged 20 years; (*d*) Left Lobe and Isthmus of Thyroid showing Multiple Cystadenomata removed from a woman aged 48 years. Dr. A. Crook: (1) Sections of Liver from (*a*) patient who died from puerperal eclampsia; (*b*) patient, full term pregnant, who died of acute pneumonia. (2) Specimen of Multiple Polypi of Cervix Uteri removed from a woman aged 61 years. Dr. W. A. Aldred: Specimen of Ruptured Tubal Gestation with Uterine Fibroid. Dr. S. H. Long: A case of Morphœa in a child aged 8 years. Mr. G. Maxted: (*a*) A case of Tumour of Iris in a girl aged 17 years; (*b*) a case of Severe Albuminuric Retinitis in a woman aged 30 years. Mr. Blaxland: A case of Osteochrondritis Juvenilis of Both Hip-joints in a boy aged 13 years (Perthes' disease).

Tuberculosis Sanatoriums for Sussex.—Both the East Sussex and the West Sussex County Councils have taken an important step towards the provision of a sanatorium for tuberculosis. On May 11th the East Sussex authority decided to acquire and adapt Darvell Hall at Robertsbridge at a cost of £23,500. Some 18 months have been expended in finding suitable premises, but the sub-committee entrusted with the work had no hesitation in recommending the Robertsbridge house, together with about 60 acres of land. Local authorities have reported their willingness to enter into agreements with regard to the scheme, and by this coöperation it is believed that the capital expenditure by the County Council will be reduced by about £3000. The Treasury grant of three-fifths of the cost will amount to £14,000. Two days later—on May 13th—the West Sussex authority with the same unanimity ratified a scheme involving the sum of £49,000. The premises and site concerned are Aldingbourne house and park in the delightful

Chichester Goodwood district Here again the finding of a suitable house and grounds had occupied much time The Aldingbourne property includes 600 acres of land, which is to be let to ex Service men as small holdings The proposed institution is to provide 50 beds, and it is estimated that a grant of £180 per bed will be received from the Government The place lends itself to future development by the erection of huts in the grounds, and the Ministry of Health states that other counties might arrange to send patients to fill any vacant beds The county of Sussex is to be congratulated on progressive action

THE King has approved the appointment of the Hon Alexander Campbell, M D, as a Member of the Legislative Council of Newfoundland, and of Dr Wroughton Gerald Heath, senior medical officer, as a Member of the Executive Council of the Presidency of Montserrat

THE Fife Education Authority decided last week to reaffirm the appointment of Robert Arno Krause, M B, Ch B Edin, as their school medical officer Objection had been raised to the appointment on account of Dr Krause's recent German nationality, and the Scottish Board of Health had suggested his replacement Dr Krause, it was stated, had lived in this country since infancy, and was naturalised some years ago

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee, held on Tuesday, May 11th, 25 cases were considered, and £218 8*s* voted to 17 of the applicants The following is a summary of some of the cases relieved —

Widow, aged 59 of lieutenant colonel, R A M C who served in England and India and died in 1905 Applicant had an accident eight years ago and is now suffering from neuritis and her sight is failing, so she is unable to supplement her income by working Has one son, married and only able to contribute £15 a year Has a pension of £90, £1 14*s* from investments £13 from friends making a total income of £119 14*s* Rent £45 10*s* Voted £5 with leave to apply again in six months —Daughter, aged 60, of M R C S Eng who practised at Cardigan and died in 1875 Health very bad through overwork, which was voluntary, in an army canteen She lives with a friend, and they share expenses Applicant is a trained nurse Income from shares £25 from property, £25 Voted £12 in 12 instalments —M R C S Eng, aged 79, widower, who practised at Kingston-on Thames Has two daughters, ages 43 and 41, living at home, the elder as housekeeper, the younger an artist who earns a very precarious living Two other daughters are nurses, and contribute £32 a year each towards the home Other income from investments £120 the capital of which cannot be used Rent and rates £54 9*s* Applicant in a very delicate state of health, as are the two daughters living at home Voted £26 in 12 instalments —Daughter, aged 68 of M R C S Eng who practised in London and Halifax and died when applicant was a child Had an accident a few years ago and is now lame and unable to work Only income an occasional gift from friends Rent 7*s* 6*d* a week for one room Relieved six times £46 Voted £12 in 12 instalments —Daughter, aged 35 of M R C S Eng who practised in Yorkshire and died in 1906 Only income 21*s* a year from investments Suffers from bad health and is now in a nursing home, and her sister has to pay expenses, which she cannot afford to do Applicant quite incapable of work Relieved three times £45 Voted £18 in 12 instalments —Widow, aged 46, of M B Glasg who practised at Sandbank, Argyll, and died in 1910 Has one son, aged 12, at school. Was left unprovided for, and is now making a living by letting rooms, from which she made £168 last year Rent and rates £68 Finds she cannot manage owing to the high cost of living Relieved once, £10 Voted £10 in two instalments

Subscriptions may be sent to the honorary treasurer, Sir Charters Symonds, C B, F R C S, at 11, Chandos street, Cavendish square, London, W 1

THE HOUSING PROBLEM IN BELFAST.—Mr. P. C Cowan, chief engineering inspector of the Irish Local Government Board, opened an inquiry in the City Hall, Belfast, into an application by the Belfast Corporation for a loan of £2,000,000 for the purpose of carrying out a scheme under Part I of the Housing (Ireland) Act, 1919, and Part III of the Housing of the Working Classes Act, 1890; and the proceedings—sometimes very stormy—lasted three days The Housing Committee of the City Council estimates that 5000 houses are now needed, but that 1500 would meet the immediate requirements As only three tenders had been received for demonstration houses the corporation want to attack the problem by direct labour 2260 applications have been made for houses through the town solicitor's department, and the average rent at which the houses were demanded was 6*s* 9*d* per week Owing to the cost of building and the lessened output of labour, the better class of houses cannot be built, the corporation allege, at a rent the working classes will pay, and as a result they recommend, to keep down prices, the erection of terrace, not detached, houses Some of the witnesses thought the corporation were taking too narrow a view of the situation, and urged that the best type of houses should be provided and the cost borne somehow, either by the State, the corporation, or the tenants themselves A great deal of unpleasantness arose because some of the witnesses accused the Local Government Board of impeding the Housing Committee of the Belfast Corporation by red tape, while the inspector denied this and said the Local Government Board had not the information supplied which it required He also found fault with the way Belfast was facing the housing problem, and said that the work of the Belfast Board of Architects was, in his opinion, most disappointing, and he declared that the corporation must submit further and carefully considered plans, so that the Local Government Board could not be accused of failing to do its part in seeing that the money was applied in the best way humanly possible

Commenting on this inquiry, a Belfast correspondent writes Apparently, so far as the housing scheme in Belfast is concerned, things have, as in many parts of England, come to an impasse The Local Government Board wants a form of house which, the practical Belfast man says, cannot be built, unless the occupiers will pay a higher rent than they are prepared to do, and the corporation declines to accept what is believed will be a financial loss, leading to increased taxation It is clear that the Government, the employers, and the Labour Party will have to take a greater share in the financial responsibility of the housing problem

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o clock on the Thursday morning of each week such information for gratuitous publication*

Manchester Children's Hospital, Pendlebury, near Manchester.—Res. M.O. £150.

Manchester City.—M.O. £450.

Manchester Royal Infirmary.—H.S's.

Metropolitan Ear, Nose, and Throat Hospital.—Two Anæsth.

Middlesbrough, North Ormesby Hospital.—Asst. H.S. £200.

Miller General Hospital for South-East London, Greenwich-road, S.E.—M.O. X ray Dept. £75. Also Hon. Asst. Ophth. S.

National Dental Hospital, Great Portland-street, W.—Hon. Anæsth.

Newcastle-upon-Tyne City and County.—Maternity and Child Welfare M.O. £700.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Anæsth.

Northampton General Hospital.—H.S. and H.P. £200 each.

Nottingham General Hospital.—H.P. Also Cas. H.S. £200 each.

Reading, Berkshire Education Committee.—Asst. Med. Inspector of Schools. £500. Sch. Dent. £450.

Reading, Royal Berkshire Hospital.—H.S. £200.

Rochdale Infirmary and Dispensary.—Jun. H.S. £125.

Rotherham Hospital.—Jun. H.S. £150.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.

Ryde, Royal Isle of Wight County Hospital.—Locum Tenens. £2 2*s.* per session. Also vacancy on Honorary Medical Staff.

Saint Pancras House and South Infirmary, King's-road and Pancras-road, N.W.—Asst. M.O. £300.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—Jun. H.S. £75.

Sheffield, Jessop Hospital for Women.—Jun. H.S.

Sheffield Royal Hospital.—Cas. O. and Asst. Cas. O. £150 each.

Sheffield Royal Infirmary.—H.P. and H.S. £150 each.

Shirlett, near Much Wenlock, King Edward Memorial Sanatorium.—Res. Med. Supt. £450.

Southampton County Borough.—Sch. Dent. £500.

Southend-on-Sea, Victoria Hospital—H.S. £200.

South London Hospital for Women, South Side, Clapham Common, S.W.—Female H.P. £100. Also Anæsth. 10*s.* 6*s.* per attendance.

Stamford, Rutland, and General Infirmary, Stamford.—H.S. £200.

Swansea County Borough.—Asst. M.O. £500.

Walsall General Hospital.—Female H.S. and Anæsth. £175.

Warwickshire County Council.—Female Asst. County M.O.H. £500.

West Bromwich and District Hospital.—Res. H.S. £200.

West Ham County Borough.—Asst. School M.O. £450.

West Riding County Council.—Asst. County M.O. £650. Two Sch. Med. Inspec. £500.

Wigan Infirmary.—Senior H.S. £250.

Wolverhampton and Staffordshire General Hospital.—H.S. £200.

Worthing, West Sussex and Chichester Joint Education Committee.—Asst. Sch. M.O. £500.

The Chief Inspector of Factories, Home Office, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at Bollington.

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for the Sheriffdom of Lanark. Applications should reach the Private Secretary, Scottish Office, not later than June 5th.

Births, Marriages, and Deaths.

BIRTHS.

CASEMENT.—On May 11th, in Dublin, the wife of Major F. Casement, D.S.O., R.A.M.C., of a son.

CRAWFORD.—At the Claremont Nursing Home, Glasgow, on 15th May, to Dr. and Mrs. A. Muir Crawford, 10, Queen's-crescent, W., a son.

DEW.—On May 12th, at Rosetta, Horsham, Marion (née Johnston), R.R.C., wife of J. Wescott Dew, M.C., M.B., B.C., of a son.

DORMER.—On May 13th, at Charles-street, Berkeley-square, W., the wife of Captain E. H. Dormer, of a son.

NORMAN.—On May 5th, at Eastwood, Strawberry Hill, Middlesex, the wife of N. F. Norman, B.A. Cantab., M.R.C.S., L.R.C.P., of a daughter.

SAUNDERS.—On May 11th, at Pembroke-street, Pembroke Dock, the wife of Dr. E. A. Saunders, jun., of a son.

DEATHS.

BLOUNT.—On May 14th, suddenly, at Lawrence-road, Hove, Arthur Blount Blount, M.R.C.S. Eng., L.R.C.P. Edin., L.S.A., aged 61.

EAGER.—On Tuesday, May 11th, at St. Aubyns, Woodbridge, Suffolk, Wilson Eager, M.R.C.S., L.R.C.P., late Superintendent of St. Audry's Mental Hospital, Melton, Suffolk, aged 75.

PACKMAN.—On May 17th, at Trimworth-road, Folkestone, Augustus T. Vance Packman, M.R.C.S., L.S.A., in his 81st year.

TREVES.—On May 18th, at Gloucester-terrace, W., Wilfrid Warwick Treves, O.B.E., B.A., M.B., B.C. Cantab., F.R.C.S., R.A.M.C.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Thursday, May 27th.

UROLOGY: at 8.30 P.M.

Paper:

Sir Peter Freyer (President of the Section): Modern Progress in Urinary Surgery.

Friday, May 28th.

STUDY OF DISEASE IN CHILDREN (Hon. Secretaries—E. A. Cockayne, H. C. Cameron, C. P. Lapage): at 4.30 P.M.

Annual General Meeting—Election of Officers and Council for 1920–1921.

Exhibition of Cases:

Members who wish to show cases are requested to send particulars to Dr. A. Cockayne, 65, Westbourne-terrace, W.2.

EPIDEMIOLOGY AND STATE MEDICINE (Hon. Secretaries—William Butler, Major Greenwood): at 8.30 P.M.

Annual General Meeting—Election of Officers and Council for 1920–1921.

Paper:

Dr. Percival Hartley and Professor C. J. Martin, F.R.S.: The Apparent Rate of Disappearance of Diphtheric Bacilli from the Throat after an Attack of the Disease.

Members wishing to dine together before the Meeting (Welbeck Palace Hotel, 7 P.M.) are requested to communicate with Dr. Major Greenwood, Lister Institute, Chelsea Gardens, S.W.1, not later than May 26th.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W.

FRIDAY, May 28th.—8.30 P.M., *Paper*:—Dr. T. H. G. Shore: Sudden Deaths on Active Service. Dr. W. M. Fairlie will show a Specimen of a Suicidal Cut Throat.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

TUESDAY, May 25th.—10 A.M., Dr. D. Robinson: Gynæcological Operations. 5 P.M., Mr. T. Gray: Ulceration of the Stomach.

WEDNESDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Morton: X Ray Department.

THURSDAY.—2 P.M., Mr. B. Harman: Eye Department. 3 P.M., Mr. Baldwin: Practical Surgery.

FRIDAY.—10 A.M., Mr. Steadman: Dental Department. 5 P.M., Sir Robert Armstrong-Jones: Mental Disease. (Lecture III.)

SATURDAY.—12 noon: Mr. Sinclair: Surgical Anatomy of the Abdomen. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M., Ward Visits. 2 P.M., In-patient and Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, May 24th.—2.30 P.M., Mr. J. B. Banister: Gynæcological.

TUESDAY.—9.45 A.M., Lieut.-Col. R. H. Elliot: Selected Eye Cases and Operations. 2.15 P.M., Selected Cases:—Mr. J. Howell Evans: Catheters—Uses and Methods of Use. 3.15 P.M., Dr. J. Oliver: The Age Incidence of Some Cutaneous Disorders. 4.30 P.M., Lecture:—Dr. Manson-Bahr, D.S.O.: The Diagnosis of Fevers, with Special Reference to those of the Tropics and Sub-tropics.

WEDNESDAY.—2.30 P.M., Dr. W. J. Oliver: Dermatological.

THURSDAY.—2.30 P.M., Mr. N. Fleming: Eye Cases. Dr. J. Metcalfe: Radiology.

FRIDAY.—2.30 P.M., Dr. C. G. Sundell: Diseases of Children.

SATURDAY.—3 P.M., Mr. Carson: Selected Surgical Cases.

Daily:—2.30 P.M., Operations, Medical and Surgical Clinics, &c.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, May 24th.—Whit Monday.

TUESDAY, May 25th.—2–3.30 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Dr. Greenfield: Cerebro-Spinal Fluid.

WEDNESDAY, May 26th.—2 P.M., Mr. Armour: Surgical Treatment of Tumours of the Spinal Cord. (I.) 3.15 P.M., Mr. Scott: The Treatment of Meniére's Disease.

THURSDAY, May 27th.—2–3.30 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Dr. Aldren Turner: Demonstration of Ward Cases.

FRIDAY, May 28th.—2–3.30 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Greenfield: Cerebro-Spinal Fluid.

Fee for Post-Graduate Course £7 7*s.* C. M. HINDS HOWELL, Dean.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Special Post-Graduate Courses in Diseases of Children, illustrated by cases, specimens, and radiograms.

1.—Dr. F. Langmead: Disorders of the Ductless Glands in Children (in the Museum)—

TUESDAY, May 25th, AND FRIDAY.—11.30 A.M., Lecture V., Disorders of the Thymus Gland. Lymphatism. Lecture VI., Infantilism.

5.—Mr. A. T. Pitts: The Pathology, Results, and Treatment of Dental Sepsis in Children (in the Out-patient Department)—

WEDNESDAY, May 26th.—4 P.M., Lecture II., The Local and General Results of Dental Sepsis.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

A Course of Post-Graduate Lectures on Syphilis is being given by various members of the staff of King's College Hospital during the present year.

FRIDAY, May 28th.—9.15 P.M., Dr. J. C. Briscoe: Syphilis in Medical Practice (Visceral Lesions other than Cardiovascular).

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton, S W.

TUESDAY, May 25th —2 P M , Dr D Grant Throat Department 2 30 P M , Demonstration —Dr Punch Cases Unsuitable for Hospital Treatment

DR. A C MAGIAN has been awarded the Médaille du Roi Albert for services rendered during the war Last year the Belgian community in Manchester presented him with a testimonial, and King Albert sent him a personal letter of thanks, while he received a silver casket and travelling bag from a number of his medical colleagues associated with the work of the Manchester French Hospital

Notes, Short Comments, and Answers to Correspondents.

COST AND PENALTIES OF CITY SMOKE

THE results of an inquiry into the cost and penalties of city smoke have just been issued by the "Air Pollution Advisory Board of the Manchester City Council" (founded in 1912), under the title "The Black Smoke Tax," and attention is drawn, amongst other matters, to the effects of black smoke on the washing bill It is asserted that the washing bill alone costs £242,705 *more than if the air was* as clean as that of Harrogate, and later, that "it would be difficult to cite any one cause so productive of loss—moral, mental, and material—as the Smoke Evil " Because of the ever present accumulating grime and dirt from smoke a labourer's wife has to spend an hour longer over the family washing in Manchester than if she lived in Harrogate There are in the city 112 616 small houses where the house wives as a rule, do their work single handed "If they all take one hour longer each week to do the washing than they would do if they lived in a clean town, the sum total of time wasted in the course of a year is equivalent to 5 850,000 hours or 668 years This is the penal sentence which the house wives of Manchester who do their washing at home serve each year for black smoke!" *The smoke tax, however, is levied also on buildings, merchandise wall paper, furniture,* clothes curtains gardens and plant life, and almost every object, animate and inanimate, in the city , also on health, as is often all too evident on the personal appearance of the city dweller

The investigation was conducted on lines similar to those adopted in Pittsburgh, U S A , where it was found that *smoke damage amounted to £4 per head of* the population per annum Questionnaires were issued to all sorts of people—architects, householders, hotel proprietors, restaurant keepers, owners of warehouses, works and gardens, and business men Architects estimated that a clean atmosphere would reduce the cost of upkeep of buildings from 20-50 per cent The answers of painters "made it clear that Manchester is a *painter's paradise*"—in a sense quite *different from* the phrase as applied to Paris by Thackeray Window curtains last only half as long in Manchester as in Blackpool The extra protection needed by printed, bleached, and dyed goods in warehouses amounts to a large sum annually Taking it all in all it is computed that black smoke costs Manchester for washing and in damage and deterioration of houses and buildings and goods at least £750 000 *a year more than if the air were as clean and smoke free as that of Harrogate*—i e , about £1 per head of the population of the city

HOW NOT TO GROW

THAT none of us by taking thought can add a cubit to his stature is, we gather from a correspondent who asks us to *let him into the secret of growing at will, a fact that still* bears repetition A growing boy, a shade under the height demanded by the Services, need not give up hope, especially if his chest and general development is poor Breathing exercises and careful physical training will often add the required inch *or more But to hold out similar hope to the* fully grown adult is to deceive him *cruelly If he holds his* knees braced back, his back erect and chin well in, a man makes the most of his inches, and not the most specious professor can add a jot, advertise he never so wisely

Our correspondent, whose height is 66 inches, and who would add a few by reason of the advantage he supposes they would confer, tells us there are many who share his *ambition*, and *not a few* who are *anxious* (for a consideration) to undertake to gratify it *He is hopeful of growing* two or three inches, while admitting that *natural growth* has stopped , the thoroughness of his investigation of ways and means deserves a worthier subject One scheme he has investigated is to thicken all the cartilages of the spine, legs ankles, "&c ," in a few weeks' time by exercise thus stretching out the natural height by several inches , two professors of Denver have a machine to do the stretching Was not something of the kind in use in the Dark Ages for the persuasion of the heretic? *We advise our lesser brethren* to have nothing to do with professional elongators of any nationality If they will learn to hold themselves erect, physically and otherwise, and abstain from contributing to the income of any who offer to make them grow, we assure them that they will not lose by abandoning the attempt to supplement Nature Inches do not make men, nor do advertisements For the rest, this is but the latest, and not the least, pathetic and lamentable instance *of the fraud and* theft which are *permitted to flourish in the guise of* advertisements with their revoltingly false testimonials '

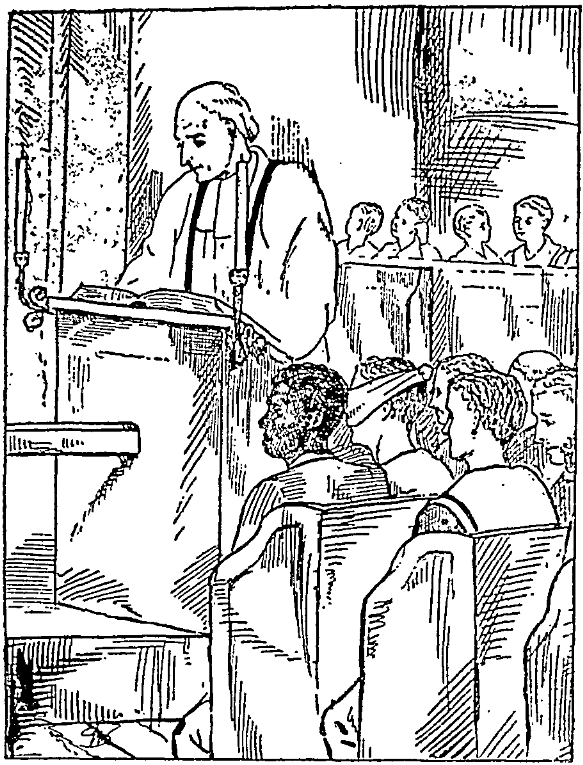
A HOSPITAL APPEAL OF THE LAST GENERATION.

THE urgent appeal to place the hospitals on a satisfactory financial footing, which appears elsewhere in our present issue, had its parallel in the times of our fathers, but a parallel only in direction and not in methods of procedure. Thirty years ago Sir Henry Burdett headed a chapter setting forth the needs of the hospitals of the metropolis with Martial's admirable motto:

"Life is not to live, but to be well."

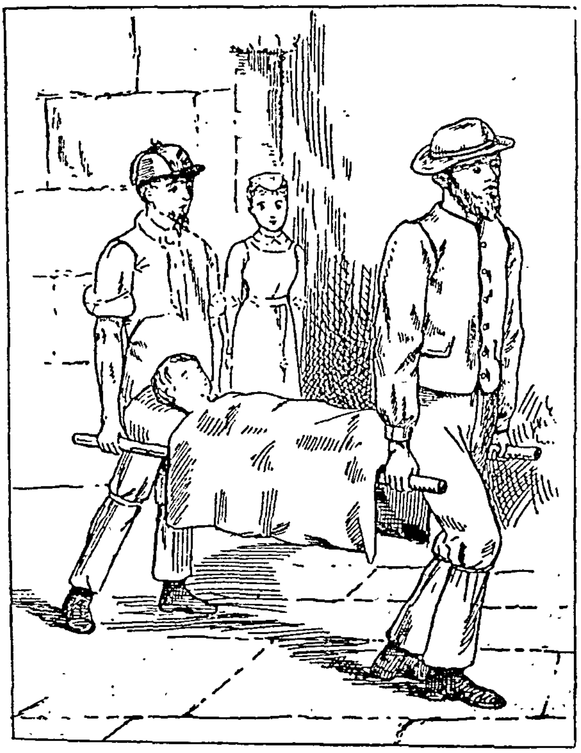
The need of hospitals, he then wrote, arises not from any special calamity which, when once overcome, is completely stamped out. "Year after year these huge institutions stand towering over the crowded, busy streets, homes of refuge for the sick, the dying, or disabled, although they are mainly dependent on chance subscriptions for maintenance. That these subscriptions come in is evident enough from the fact that the institutions continue to remain open."

FIG. 1.



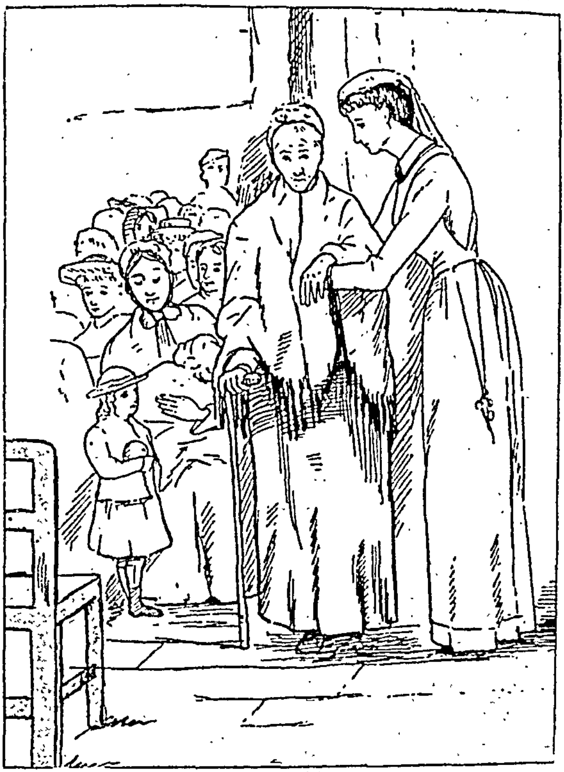
SEAMEN'S HOSPITAL, GREENWICH.

FIG. 3.



CHARING CROSS HOSPITAL.

FIG. 2.



WESTMINSTER HOSPITAL.

Each generation has its own particular method of dealing with the problem of hospital finance and of appealing to the public. We reproduce here three of the illustrations designed in 1890 to set forth the particular services to humanity rendered by three metropolitan institutions. The first was issued by the Seamen's Hospital Society for its "Dreadnought" Hospital of 225 beds at Greenwich, "free to the whole maritime world." The wide range of age and nationality among its patients emerges clearly enough from the picture. The second shows a corner of the out-patient room of the Westminster Hospital (205 beds), with the evident intent of making known also the "large and flourishing training school and home for nurses." The third instantly turns the mind to the patients of Charing Cross Hospital, "more than two-thirds of which are cases of accident or emergency." The stretcher-bearers and nursing staff of the period are doubtless correctly depicted.

We obtain our realism to-day in a very different manner, and we wonder whether our statistics and balance-sheets speak as clearly. There was, of course, no comic side to these pictures when they appeared.

IMPROVED TONGUE FORCEPS.

THE tongue forceps here illustrated is an improvement on the older model, inasmuch as rotation is prevented by the two wings. The tongue is gripped half an inch from its tip by the forceps. To extrude the tongue the forceps are swung round on the puncture point as centre to opposite cheek. The forceps are constructed to lie flat on the face, thus preventing any leakage when using a closed anæsthetic mask. Messrs. Allen and Hanburys, Ltd., are the manufacturers.

Goulstonian Lectures

THE PRINCIPLES OF MEDICAL SCIENCE AS APPLIED TO MILITARY AVIATION.

Delivered before the Royal College of Physicians of London

BY J. L. BIRLEY, C.B.E., M.B., B.CH. OXON., F.R.C.P. LOND.

LECTURE I.

Delivered on March 9th, 1920

MR. PRESIDENT AND FELLOWS,—I am deeply conscious of, and I desire to thank you for, the honour you have done me in offering me this lectureship, at the same time, I am only too well aware of my limitations for fulfilling the onerous duty involved. Instead of employing these past few years in making original observations and gaining, as one had hoped to gain, some special knowledge in a particular branch of our science, we have been thrown into the rush of war, to be deluged by surprises, confronted with undreamt of situations, and expected at a moment's notice to pronounce expert opinions on subjects concerning which we would sometimes have preferred to confess a profound ignorance. Under these circumstances I felt myself strictly limited in the choice of a subject, and it came therefore as a relief to discover that the subject which I was forced to choose, scattered and diffuse as it is, would not be altogether distasteful to some of you.

It was the fortune of war, indeed the good fortune, which during the later stages of the first great battle of the Somme brought me into contact with our flying services in France; it was similarly good fortune to be allowed to remain with them until victory had been won.

The subject under discussion is, on the face of it, a new one, and I approach it with some diffidence, more especially since other workers in the same field have been tempted into making somewhat sweeping assertions which have failed to stand the test of subsequent investigation. As a matter of fact, the medical aspects of aviation embrace no new discoveries and necessitate no revolutionary doctrines, but rather insist on the proper application of well recognised scientific principles. The only novelty which can reasonably be claimed for these lectures is that they deal not with the causes and results of disease, but, on the contrary, with the effects produced in large numbers of healthy young men as the result of employment in an unnatural and dangerous occupation. In brief, they attempt to describe the reaction of the normal individual to an abnormal environment.

In this connexion I cannot refrain from remarking on a difficulty which must have confronted many of us. It was an everyday experience that when dealing with sickness or injury the medical officer possessed the complete confidence of his executive colleagues, but when it came to a question of offering advice on matters not directly connected with disease the reverse was the case. It is both easy and popular to criticise this conduct, but it seems to me readily comprehensible. The experienced soldier, not without reason, considered his credentials for knowing "what his men could stand" at least as good as those of his medical colleague. He argued to himself that a doctor was in his element when he had someone ill to attend to, and consequently out of it when dealing with fit men. This criticism had a great deal of truth behind it. We were, to put it frankly, ill equipped to answer the conundrums with which we were confronted. Trained to concentrate our attention on the lesion and its treatment, we were inclined to pay insufficient attention to the functional disturbances which it evoked, and none at all to the bodily reactions which aim at counteracting its effects. In war, however, function is everything, for in terms of function one measures efficiency. The capacity for mental and physical endurance displayed during the war was a source of universal pride, while to us in particular it provided in addition the stimulus for investigating the compensatory processes by which this endurance was rendered possible. In no field was progress more evident than in the psychological, and it is with the psychology of military aviation that this lecture is mainly concerned.

THE MILITARY DUTIES OF THE FLYING OFFICER.

If we wish to understand the psychology of the pilot and his observer, and to gain their confidence, we must have a clear idea of the work they have to do and the conditions under which they do it. The development of these activities, like the other subjects of these lectures, can best be studied historically.

In the earlier days of the war the aeroplane was used exclusively for purposes of reconnaissance—to report movements behind the enemy's lines and to assist the artillery in the location and, if possible, in the destruction of suitable targets. As the war proceeded reconnaissance was developed chiefly by the use of aerial photography and artillery cooperation by the use of wireless telegraphy. The next advance was to carry by means of bombs an offensive warfare behind the enemy's lines with a view to disorganising his communications, disturbing the productivity of his factories, and undermining his morale. This form of activity gave birth to night flying. As, however, enemy aircraft were employed on precisely similar duties, retaliatory measures began to develop on both sides. The anti aircraft gun, though capable of interfering with was powerless to put a stop to aerial activity, and it soon became apparent that this object could only be obtained, supposing it could be obtained at all, by the aid of aircraft itself. In this way arose fighting in the air—i.e., the destruction of aircraft by aircraft—and it was this aspect of aerial warfare which naturally appealed to the public imagination to the exclusion of what always remained the more essential forms of aerial activity. As the war proceeded aerial activity, although becoming greatly intensified owing to the increasing numbers of machines employed, maintained the characters alluded to. One further development, however, took place. This consisted in the active cooperation of aircraft with the infantry within the battle zone itself. For this purpose aeroplanes were employed at very low altitudes and within easy reach of hostile machine gun fire to assist bodies of infantry in maintaining contact with one another, and, further, by the use of machine gun fire and small bombs to harass the enemy in every possible way.

This brief résumé will serve to demonstrate the variety and dissimilarity of tasks with which our flying men were confronted, a point of considerable psychological importance.

ORGANISATION.

As the first Somme battle revealed the immense possibilities of aircraft in war, so it first drew attention to the medical requirements, or perhaps it would be more correct to say to the medical defects, of our flying service. Not only were battle casualties greatly on the increase in proportion to the numbers engaged, but losses from sickness as a result of nervous breakdowns began to reach alarming proportions. Moreover, officers who had previously been sent home for a rest were not coming back to France in the numbers that had been expected, or else, when they did return, exhibited less powers of endurance than they previously possessed.

Up to this time there was practically no medical organisation in the field or at home directed to the particular needs of the flying service. The need for such was, at this time at any rate, almost entirely a psychological one, while the reason for its absence was also, in my opinion, psychological. It was realised, of course, that warfare in the air threw a great and increasing strain on those engaged, but the belief was fostered, inspired partly by hope and partly by the fine qualities of mental discipline engendered by military training, that strain could be overcome and kept at bay by the exercise of will power for an almost indefinite period. It was difficult to realise that will power like the rest of one's mental faculties was not immune to exhaustion.

After two years of war officers were still being accepted as pilots and observers on the flimsiest medical examination or even on none at all, while those who were systematically examined were adjudged on standards which were originally laid down from the point of view of the ability of the candidate to march and to shoot from his right shoulder. It accordingly happened that a prospective candidate might be accepted with a blind left eye or be rejected on account of the possession of flat feet. This anomaly was corrected by the institution of a Central Board for the examination of all candidates for the flying services. That the new standards set up by this hard-worked body gave rise to even greater criticism than those which they replaced will be referred to in a subsequent lecture. Suffice it here to say that such a state of affairs was, to my mind, inevitable.

In the field very little organisation was necessary to meet the requirements. The first step was to obtain suitable medical officers for duty with groups of squadrons, with the main object of acquiring a personal knowledge of all officers under their care; those with previous experience of battalion work, and therefore with knowledge of the psychology of the fighting man, were particularly sought after. It was next necessary to obtain at some convenient base a number of beds reserved for the reception of flying personnel, whose disability appeared to be directly related to the peculiar work on which they were engaged. This hospital unit rapidly became one of the busiest in France, thanks to the tireless industry and enthusiasm displayed in its inception and continuation by the late Dudley Corbett and H. C. Bazett. The most important step, however, was to maintain constant liaison with commanding officers, to make them realise that the science of medicine had a sphere of usefulness beyond that of dealing with the sick and wounded, to convince them that it was a necessary factor in promoting efficiency and maintaining discipline, and having excited their interest to obtain what was absolutely essential for our purpose, their sympathetic coöperation. During the months from August, 1917, to November, 1918, inclusive, close on 2000 flying officers passed through this special hospital unit; of these over 40 per cent. were deemed to be suffering from the fatigue inseparable from active service. In order to interest commanding officers in the medical aspects of aerial warfare they were encouraged not only to visit this unit, but also to send a confidential report on every patient admitted. In this way the large majority of them were stimulated into taking an intelligent interest in the physical and psychical welfare of those under their command, and many by becoming extraordinarily astute psychological observers afforded us valuable assistance. Individual psychological study was possible in the air service to a degree unknown in the infantry; this was so not merely because of the comparatively small numbers involved, but also on account of the high degree of individualism which service flying entails and encourages.

TEMPERAMENT.

A great deal has been written about "the flying temperament" as if it were something sui generis, and it has been suggested, and in some quarters even claimed, that it is possible by medical means alone to discover its presence and lay bare its absence. We all know what we mean by temperament, and yet to define the particular qualities going to make up the temperament necessary for success in any given walk in life is not one which can be lightly undertaken.

A. *The Flying Temperament.*

It has been elsewhere[1] pointed out that the temperament for flying per se was of little importance in the field, since those devoid of it did not, as a rule, reach the active service stage. One can hardly be surprised that a proportion of presumably normal individuals dislike flying, for there is after all a certain feeling of insecurity of tenure in the air which becomes more pronounced during prolonged flights. I understand that the majority of those who since the war have made flights extending over several hours have experienced a definite sense of relief on landing. It is, therefore, doubtful whether we are justified in classifying this particular distaste among those pathological phenomena known as phobias. A curious feature of those cases which have come under my notice has been a feeling of increasing insecurity with increasing altitude. Such individuals remained comparatively comfortable up to one or two thousand feet, but above this height they were overtaken with a consuming dread. One particularly gallant officer vainly attempted to conquer this weakness by covering up his altimeter with his flying cap. There appeared to be no correlation between this "altitude neurosis" and the discomfort experienced when gazing over a precipice or looking down from a high building. There were, however, a few individuals who, greatly to their credit, in spite of an ever-present sense of insecurity in the air, not only learnt to fly, but so mastered their feelings that they became successful military pilots, gaining promotion in the service and even winning decorations for gallantry.

The attempt to determine by physical and psychological examination the possession, or otherwise, by an individual of the temperament for flight is one with which I must confess to be little in sympathy as being one beyond our reach. Even an individual's keenness to fly may be misleading owing to the lack of correspondence between anticipation and realisation. Flying aptitude should rather be compared with any other form of activity requiring perfect coöperation between eye and hand. Such coöperation is best exemplified, and incidentally may be greatly developed, by the playing of games. "Flying," as Dr. Henry Head has very correctly said, "introduces no elements which are not in evidence in riding a motor-bicycle, game-shooting, cricket, or golf."[2] But two individuals may be equally good at the same game or the same sport, and yet their methods may have nothing in common; we say their "styles" differ. So too their temperaments may differ widely and yet the end-result be the same. At the risk of being accused of levity I would in all seriousness ask what possible resemblance could be traced in the physical or temperamental qualities possessed respectively by Dr. W. G. Grace and Prince Ranjitsinhji? Just as the latter could break all the rules of batting with impunity, so can some pilots break at least many of the rules of flying without at the same time breaking their necks. To postulate one temperament and one only for flying, or for any other form of coördinated activity, surely implies a too mechanical and stereotyped habit of mind. We cannot at present identify the potential cricketer or mathematician except by watching how the former catches a ball and how the latter does sums, and the same principles would seem also to apply to the art of flying.

Nevertheless, the attempt to define and isolate this elusive quality, the flying temperament, has been productive of a vast amount of pioneer work in the countries at war, more, perhaps, in France, Italy, and America than here. Large numbers of experimental values have been obtained and correlated with the subsequent success or failure of the candidate.[3] For the so-called "kinæsthetic ability," for example, no less than 32 values were ascertained by the French authorities for each candidate, all of them connected with the general function of equilibration. These values, however, were not actual measurements of efficiency, but merely determinations of certain reactions assumed to be indicative of efficiency. It cannot be said that in this field, at any rate, the results were convincing; the equilibration tests employed in America, for instance, gave the same correlation with success as a pilot as did the candidate's ability to drive a motor-car. Similar correlations were sought for by statistical and routine analyses of character and intelligence, but again with indecisive results.

Psychometric tests.—The most promising line of approach appeared to be that afforded by the psychometric tests, which, under the direction of Camus and Nepper, achieved considerable fame in the French flying service. These tests were based on the assumption that "aviation demands the special quality of rapid decision which is measurable by the candidate's psychomotor reactions." While not denying that rapidity of decision is most desirable, I would emphasise what has been repeatedly pointed out to me by numerous flying friends (some of whom, it is true, failed at these reactions) that, whereas a clear judgment and correct rather than quick decision will make all the difference in a tight corner, as in any other activity, flying under peaceful conditions in the absence of untoward events is a sedate procedure, bordering at times on the monotonous. They also point out that the bodily movements necessary for controlling an aeroplane are methodical and deliberate, and not to be compared in speed with those necessary for playing a game such as racquets.

Psychometric reactions are divisible into two main groups—simple and complex or choice. In the former the stimuli are of the most elementary character, plain visual, auditory, or tactile impressions. These reactions are recorded by means of the D'Arsonval chronometer. The average normal values are as follows: Visual 19/100ths second, auditory 14/100ths, and tactile 14/100ths. A satisfactory reaction also entails but little variation between the individual responses in the whole series. The responses are slowed in conditions of exhaustion and after illness, a fact which was corroborated on our own pilots. Although I have no statistical evidence that these simple reaction times are an indication of flying aptitude, I understand that the results obtained on some of the most distinguished and successful fighting pilots in the French air service strongly supported such a view. But even so, there is still the possibility that these tests afford an indication not so much of aptitude for flight as of ability to fight a gun in the air, an operation which especially calls for great rapidity and dexterity of movement. Of the three reactions, that to auditory stimuli would seem the most delicate.

In the complex or choice reaction the subject is not limited to one movement, but has to select between two or more according to which stimulation occurs. Theoretically this would appear to give a better indication of the quality of rapid decision, in which complex psychical processes must necessarily be involved. From an investigation carried out on these lines it certainly appears that the correlation with flying aptitude increases up to a point with the complexity of the reaction [4]

B *The Fighting Temperament*

In war the aeroplane has to be looked upon as a device whereby the mobility of the individual is so increased that he is able, directly or indirectly, to inflict losses on the enemy in the enemy's territory The military pilot must therefore possess the combatant spirit This is not necessarily associated with the aptitude for flight The most skilful pilot might be, and sometimes was, valueless as a fighting force, while, conversely, lack of technical skill was very far from being equivalent to lack of military value indeed, several of those pilots, the memory of whose conspicuously successful gallantry will endure, could not be considered first class fliers, while one, at least, was definitely indifferent Hence what chiefly mattered in the field was the fighting temperament This is a theme, however, which cannot profitably be dealt with here

PERIODS OF EFFECTIVENESS

Confining our attention now to an officer's effectiveness as a fighting force, and not to his skill as a pilot, from the purely technical point of view, it was found that the degree of effectiveness varied greatly at different states of his military career These stages may conveniently be compared to the seasons of the year

The Period of Inexperience

This is the flying officer's spring and is chiefly occupied in learning to fly, an aspect of which I have no personal knowledge Its importance is obvious, and it provides a fruitful field for psychological study But this stage does not end when the individual reaches the fighting line as a fully qualified pilot, for he is still without practical experience of war During the next two months he passes through the most critical stage of his career, gaining experience only too often at the cost of his life To realise this it is only necessary to consider what may be called the military age of a flying officer, his birthday being the day of his arrival in the fighting line If, for example, we wish to determine the average military age in any squadron or group of squadrons we have to determine the total number of weeks served by each officer since his arrival in the squadron and divide the total by the number of officers in the squadron or group Similarly, we can determine the average military age of those who become casualties as the result of battle, accidents sickness, &c The following figures are only approximate but for our present purposes sufficiently accurate

On the Western front the average military age of casualties due to battle and accidents combined was for the whole of 1917, 2 months and 18 days, for the five winter months the military age was as much as 3 months 4 days, but for the summer (fighting) months 2 months and 11 days Or, to put the matter differently, of the battle casualties sustained during the fighting months of 1917, 35 05 per cent occurred among officers who had been less than one month with their squadrons 25 60 per cent among those who had been less than two, and 12 32 per cent among those who had been less than three The corresponding figures for the whole of 1918 up to the armistice were as follows 26 43 per cent under one month 27 97 under two months, and 14 97 under three months That is to say, during 1917 and 1918 roughly 70 per cent of the casualties sustained in battle and in accidents occurred among officers who had completed less than three months of active service These figures must not be taken too literally First, it must be remembered that officers did not remain on an average much more than six months in the field before being sent home for a rest Secondly, there were always larger numbers of "young" officers in a squadron than "old' ones, and therefore the incidence of casualties among the former is not as heavy as the figures quoted would make it appear Remembering, too, that casualties had nearly always to be replaced by the inexperienced, a period of heavy casualties by lowering the average military age of a unit tended to increase its vulnerability

But altogether apart from figures it was the unanimous opinion of all unit commanders that a pilot s, especially a fighting pilot s, first two months of active service constituted the critical period, during which he was more likely to become a casualty himself than to inflict casualties on the enemy The period of inexperience then corresponds to the period of minimal military effectiveness and of maximal vulnerability, and particular stress has been laid on it, not so much because it contrasts so vividly with the ensuing period, but because unless it is appreciated it is impossible to understand the psychological atmosphere of a flying squadron as a whole

The Period of Experience

Having escaped the dangers surrounding his first two months, the flying officer enters upon the summer of his career, a period of confidence and self assurance, of initiative and dash, of skill and wise discrimination, of success and achievement His vulnerability is now relatively slight and his military effectiveness at its zenith The length of this stage is naturally variable, depending on the constitution of the individual, the amount and character of his work, and the success he achieves in doing it The inspiration born of success especially helps to prolong it Nevertheless, it is absolutely certain that it cannot last indefinitely, autumn, or the period of reaction, must supervene sooner or later And it will be just here that the ability to make accurate psychological observations and deductions, whether in a unit commander or his medical colleague, is of such vital importance For if the successful officer can be spared from experiencing in too great a measure the mental conflict which characterises the period of stress, if he can be rested at the crucial moment, he will in a comparatively short time again be fit to return to the fighting line, not to embark again on those critical two months of danger and inexperience, but to jump with one bound into a second period of confidence and efficiency The appearance of one such individual might even rally a broken and discouraged squadron

The Period of Stress

The mental strain inseparable from warfare in the air presents the same picture, both in its development and its end effects, as that which occurs in other combatant branches of the service, it is only the colouring which is different It will be worth while briefly to consider a few practical points peculiar to the flying service which modified the development of the condition of stress It was a curious feature about a fighting squadron, comprising only eighteen flying officers, that it could be made or marred by two or three individuals especially if they were in the position of leaders These few set the pace often it is true, to the detriment of those who attempted to follow If, now, one of these individuals were permitted to remain when the period of stress had become definitely established, and his efficiency was on the wane the results might be disastrous His leadership in the air became less effective, the offensive spirit dwindled, and the new arrivals in the unit obtained an entirely false impression of the standard of work expected from them A leader therefore, whose effectiveness was lowered by fatigue could as easily mar a squadron as one in the prime of his career could make it Nevertheless, his commanding officer was often reluctant to replace one who had served him so long and so well, often enough he had already acquired a reputation to shake which something more was demanded than a falling off in achievement, too often but generously regarded as a temporary run of ill luck

Secondly the type of flying largely determined the onset of stress In artillery squadrons, where the mind was fully occupied in registering targets signalling the progress of operations, &c and pilot and observer enjoyed each other's companionship, complete efficiency was retained in spite of the dangerous character of the work, up to eight nine, or ten months, or even over a year In fighting units however where the whole object was to destroy the enemy in the air or to take part in the infantry battle, the effective period was much less

Thirdly, the irregular hours of sleep during the summer, with the nights disturbed by the aerial activity of the enemy, were an important influence in hastening the onset of stress The question of sleep was particularly difficult to arrange in squadrons employed exclusively by night

Again, all flying is in a sense fatiguing, in that it demands attention but the fatigue experienced is in inverse proportion to the skill of the pilot and the efficiency of the aeroplane The importance of the latter factor in war is very real The psychological effect of the appearance on one or the other side of a machine superior to anything that can be pitted against it was frequently in evidence on the Western front In the same way flying over enemy territory with an engine the reliability of which was open to question was an operation peculiarly adapted to the rapid acquisition of a state of anxiety

The question of altitude will be dealt with in a subsequent lecture Here it is only necessary to say that flying at altitudes over 13 000 to 15 000 feet was a factor which definitely accelerated the onset of nervous fatigue

The most important psychological factor however, peculiar to the flying service was its individualism Flying in formation diminished but certainly never abolished this outstanding feature A flying officer relied essentially on his own skill his own courage his own resolution, and his own sense of honour and of duty He lacked and most certainly missed the inspiration born of responsibility to his men and that intimate comradeship in danger which for the infantry officer served as sources of support and encouragement [5]

THE MENTAL REACTION.*

It is not proposed to discuss this subject in any spirit of controversy, but to regard it as a perfectly normal reaction to a very abnormal environment. That this reaction is now comprehensible is largely due to the advance in our psychological knowledge which was literally forced upon us by the war.

It will be recalled that man's earlier interpretation of the universe, and therefore his attitude towards disease, was essentially an animistic one, and all disease was ascribed to spiritual agencies. This interpretation was gradually replaced by explanations of a materialistic kind, so that the production of disease was ascribed in an increasing majority of instances to material agents, and only where no such explanation seemed possible were spiritual agencies still invoked to account for its presence. The concept of the activity involved by these latter agencies was, however, very different from what we now understand by "mind." It was the impetus derived from the study of the phenomena of hypnotism, introduced from the East, which led modern thought to the recognition of the *mental* factor in medicine. In the course of these studies it was found that hypnotism might offer the means of reaching experience "which had been so completely buried that by no effort of the will could it be recalled."[6] It was left to Freud to demonstrate that these buried memories could be recalled without the aid of hypnotism by means of what he called "free association," the necessary clues being usually provided by dreams.[7] By the knowledge derived from his analyses he was able to put forward for the first time a definite scheme of the unconscious region of the mind and its relation to the conscious. It accordingly became possible to correlate events in the sphere of the conscious with events in the sphere of the unconscious, and so to adopt in the sphere of the mental the principle of determinism which had so long assisted the progress of physical science. It is the special value of Freud's work that the student of mind can now believe that every psychical event has its psychical antecedent, and so believing will have the patience and courage to probe deeply into the history of his patients.

Partly independently, but partly because of Freud's work, the great importance of the instinctive or emotional aspects of mind was becoming increasingly recognised before the war, and the emotional factor in neurosis was coming to be regarded as the expression of some instinctive tendency which had to be repressed on account of its incompatibility with social standards. It is well known that Freud was led to the conclusion that the mental experience which tended to be so suppressed was nearly always connected with the sexual instinct, and the exaggerated importance attributed to this factor, more especially by his disciples, not unnaturally rendered his views unacceptable to the general body of medical opinion both in this country and in France. The war, however, while accentuating the truth of Freud's main assumptions, has made it possible to discard the dominating importance of sex, and to substitute in its place the still more fundamental instinct of self-preservation.

In dealing, therefore, with the reaction inevitable in war we are dealing first and foremost with the defence mechanisms developed by the individual for countering his natural instinct of self-preservation. When these mechanisms are weakened by shock or prolonged strain, and the instinctive tendency comes into conflict with social standards, a condition of neurosis results. Among the instinctive or affective aspects of mind which particularly concern us the emotion of fear naturally takes pride of place.

The most frequent mode of reaction to actual danger in man consists in an extremely complex reflex action which so adjusts the bodily functions as to render the individual better fitted to meet and overcome the danger. In this, which we may call the physiological reaction, the emotion of fear takes no part and fails to appear; we say a man is "cool in the presence of danger." A second mode of reaction consists in the replacement of the emotion of fear by the emotion belonging to the instinct of aggression—namely, the emotion of anger—and we say a man "sees red." In both modes of reaction, however, although fear is not felt, we may, for many cogent reasons, confidently assume that it is potentially present, but in a state of suppression. It may, however, and indeed does, appear on the surface when the mechanism of suppression is lowered by shock or strain, or when higher control is weakened, as, for example, in the waking state.

These considerations lead us to the comprehension of the two earliest symptoms of the mental stress induced by war, first the nightmare, and secondly the occurrence of actual fear or of apprehension under circumstances in which these had not been previously experienced. These symptoms the sufferer keeps to himself, and so begins an entirely new process, the conscious repression of fear and apprehension, which are regarded with shame, and as much as possible evaded. The slang nomenclature to which the war gave birth, especially the substitution for the word "fear" of quasi-humorous expressions, is in itself evidence of the desire of the individual to shun the consciousness of fear. This conscious suppression of fear only serves, however, to increase the strain and fatigue which has led to the failure of its unconscious suppression, and a state of persistent anxiety gradually develops, characterised particularly by loss of sleep and various disturbances of physical health.

"Wind Up": A Clinical Picture.

The clinical picture presented by an officer whose mechanisms of defence have given way under the strain of war is characteristic. In its earlier stages, however, it is usually entirely subjective, and its presence can therefore only be discovered by a medical officer whose personality compels the sufferer to come to him in confidence and disclose his troubles. The tired pilot may under these circumstances complain of having lost some of his keenness; he has recently been dissatisfied with his work, and for the first time has begun to wonder when it will be his turn to go home; he has already been out over six months. He has not been quite sure of himself in the air lately, and to make certain that his confidence for flying is unshaken he has attempted to reassure himself by proving his ability to execute various manœuvres dangerously close to the ground; the result has not been a success. Perhaps it is all due to the mess having been unsatisfactory; he thinks the tone has gone down; anyhow, he has been off his food. He has only just recently recognised that he prefers to leave the mess after meals and lie down and read a book in his own room. His sleep is less sound than it used to be; he takes a long time to get off and has lately been dreaming. At first the dreams were not unpleasant, merely that he was making bad landings and getting laughed at. Then they began to worry him; he would dream of long-forgotten experiences in the trenches, or that he was "brought down" and taken prisoner; and he hardly likes to mention it, but once he was "brought down" in flames, and woke up in terror shaking all over. His administrative work on the ground has been a labour instead of a pleasant duty; he has had a row with his sergeant, and he feels the "C.O." is losing faith in him. The new pilots from England are not altogether satisfactory; his responsibilities weigh heavily on him, and he thinks that the death of a member of his flight was avoidable, and perhaps was his fault. He admits that he is conscious of having to force himself into the air, and is inclined when leading a patrol not to "go for" things which he would have done without hesitation a fortnight ago. Perhaps flying has affected his heart; he has had palpitations lately, has been short of breath on exertion and easily tired. Anyhow, the whole thing is a complete mystery to him, although he is sure it is only temporary and the doctor will give him something to put him right. And so, seeking for trivial causes in explanation of a fundamental change, reluctant to acknowledge what he dreads—what, moreover, he has publicly condemned in others—equivocating, pursuing false hopes, and evading the real issues, this eminently brave man will frequently conclude with the appeal, "Don't tell me its 'wind up.'"

It is at this stage that the medical officer can obtain results of incalculable value to the individual, both as a patient and a soldier. The condition is essentially mental, and treatment must be directed to the mind. By assuring him that there is no cause for shame or reproach but rather the reverse, and by inducing him to give up the process of voluntary repression, he can so prepare the soil that during the necessary rest which he will insist on the normal mechanism of defence will be rebuilt and the individual restored to perfect health and efficiency. Moreover, having once experienced the condition and made to understand it fully and frankly, the officer will in future be enabled to understand its appearance and recognise its onset in his companions.

When the condition is allowed to progress unrecognised the state of anxiety increases. The more stout-hearted the sufferer the longer he disregards Nature's danger signals. He becomes irritable, unsociable, morose, losing his inspiring personality, and adopting a black outlook on things in general. Although he feels tired, he is excitable and restless; unable to sit down to read or write, he must needs always be pottering about the aerodrome looking at the weather. To keep himself going he smokes to excess, or may even come to rely on alcohol. If he meets an enemy formation on patrol he either turns tail or attacks recklessly, too tired to think about manœuvring In the last stage the noise of the engines on the aerodrome distresses him, he cannot bear to see a machine take off or land, and he even hates to hear "shop" talked Sooner or later he must give in The career as a war pilot of an individual who reaches this extreme stage is irrevocably finished

---

* In this section I have drawn freely from two sources: (i.) two contributions by Dr. W. H. R. Rivers—(*a*) Mind and Medicine, a lecture delivered on April 4th, 1919, and published by Longmans, Green and Co., and (*b*) "Wind Up," an article written for the use of R.A.F. medical officers; (ii.) an unpublished paper entitled "Flying Fatigue and Efficiency," written in France in August, 1917, by my late friend and colleague, Dudley Corbett.

Prophylaxis and Cure

It would seem at first sight an easy matter entirely to prevent the development of the anxiety state by anticipating it In practice, however, such a course was well nigh impossible Some of the reasons why this was so can be inferred from what has already been said, they were not within the control of any one man, but were rather the inevitable consequence of the way in which the war developed It was, however, recognised that the principle of short shifts was applicable here as in all other communities where industrial fatigue was to be expected, and in this way it was found possible perceptibly to reduce the *permanent* wastage from this cause, and materially to shorten the interval between an officer's admission to hospital and his return to the fighting line

During the closing months of the campaign, when the drain on the man power of this country had become very severe, the anxiety neurosis became a more prominent and far more difficult problem than ever before, although in a somewhat modified form The type of manhood that was being pressed into the service inevitably deteriorated In these individuals, and essentially as a result of the lack of that mental and bodily education which more than anything else assists the formation of character and the gradual development of the psychological mechanisms of defence, the powers of resistance were insufficient The majority of them mentally immature, many of them physically so, unaccustomed to rely on themselves, looking rather for things to be made easy for them, lacking initiative, and naturally apprehensive, through no fault of their own they were ill equipped for the duties for which they had been hurriedly trained Moreover, the qualities requisite for a successful fighting pilot are as relatively rare as they are splendid, and it was particularly in fighting machines that the great numerical expansion of the air service had taken place These individuals, then, never having acquired that unconscious suppression of fear which in their more fortunate comrades of tougher calibre had come into existence in early boyhood, broke down early, and had to be eliminated as quickly as possible For the condition of anxiety which so rapidly developed in these misfits I have elsewhere proposed to substitute for the term "stress" that of "distress"

The line of treatment to be adopted in the states of strain imposed by war follows closely from what has been said as to the causative factors, mental and bodily calm have to be restored It is first necessary to eliminate the affective state due to the disturbing emotion of shame, and, secondly, to persuade the sufferer to discard the process of voluntary suppression Two other therapeutic agencies may be mentioned The first, that of self knowledge, by which, among other things, the sufferer is brought to understand elements of conscious experience which are being misinterpreted, the second and more important, the agency of self reliance, by which he is persuaded frankly to face his troubles instead of running away from them In other words, we have first to assist the patient suffering from stress to understand his troubles, and then to appeal to his common sense and his character, it is easy to understand why, in the condition of distress, the results of mental therapy must be disappointing

THE PHYSICAL REACTION.

The disturbances evoked by abnormal psychical states in the physical sphere may be profound, and the recognition of this fact, forced upon us by the war, seems likely to play a prominent part in influencing the future progress of medicine. There need be no difficulty in understanding this if we remember the profound physical effects invoked by emotional states, amounting in animals to complete muscular paralysis

The incidence of these disorders varied greatly Many officers after a long and arduous spell of work, though conscious of an altered state of mind, showed little manifest disturbance of physical function One of the earliest signs of stress was revealed in a loss of weight, amounting in some cases to over a stone in two or three weeks Clearly metabolism, as in exophthalmic goitre, was tuned to a high level, and it has also been shown that the oxygen consumption per minute was often above normal in these cases[9] In a large number of individuals, however, in whom a state of anxiety had become definitely established, all or some of the physical changes shortly to be mentioned were found to exist These disturbances were all characterised by a loss of central nervous control, resulting in conditions the main feature of which was overaction[1] It was our practice in France, a practice originating in the supposition that repeated exposures to high altitudes might induce changes in the circulatory and respiratory systems, to investigate these systems with particular care It soon became apparent, however, that the disturbances which were frequently found could not fairly be attributed to such exposures alone, since they were common to the majority of individuals suffering from mental strain, in many of whom high altitudes could not have been an ætiological factor

In the circulatory system a rapid pulse, throbbing cardiac action, a pulse rate and blood pressure both unduly susceptible to changes in posture and slight exertion, and a large pulse pressure were the rule In such cases, even when resting, the heart appeared to be working at full pressure with no reserve to draw upon when an extra effort was demanded of it A short walk along the road was sufficient to produce physical distress

In the respiratory system the shallow rapid breathing, small tidal air, diminution in vital capacity, and high ventilation per minute all pointed to an excessive irritability of the respiratory centre, and consequent diminution of respiratory reserve power[10]

In the neuro muscular system loss of tone of the abdominal wall, as evidenced by stomach splashing and diminution of expiratory force, tremors of the hands and tongue, and disturbances of static equilibrium were all indicative of an escape from nervous control

The increased output of adrenalin with the production of hyperglycæmia,[11] which has been shown to occur in various emotional states, probably results from excessive stimulation of the sympathetic system[12] In the same way may be explained the remarkably acute and at times alarming digestive disturbances, simulating the picture of duodenal ulcer, which occurred so frequently, and also the abnormal action of the vagus on the heart[13] and lungs[14]

It is impossible to escape the conviction that in a large proportion of these cases this condition was essentially mental (emotional) in origin This view in no way conflicts with the theory of toxæmia favoured by Lewis to account for the similar condition in the foot soldier[13], on the contrary, following the influenza epidemic of 1918 numerous officers were found to be suffering from a condition clinically indistinguishable save for the absence of anxiety, from that which has been briefly described

The emotional factor in the production of physical disturbances is well illustrated by a series of pilots who had been concussed as a result of a 'crash' with loss of consciousness Of 24 cases one half, several of whom could remember nothing about the accident, seemed little affected, the response of the pulse to change of posture and to exercise was normal, there was no loss of abdominal tone, no tremor, and a comparative absence of symptoms All returned to duty after a short rest and did excellent work The other half all had vivid memories of their accidents and were definitely "on edge", their pulse rates were high and unstable, abdominal tone was poor, tremors were prominent and headache persistent All were evacuated to England and none of them returned

SUMMARY.

The experiences which have been studied serve to emphasise the predominating influence of the higher nervous centres in man The lower centres in their turn transmit these influences to every organ in the body, and we realise as perhaps never before that our bodily health and bodily activities are at the mercy, so to speak, of events taking place in our cerebral cortex

WELSH NATIONAL SCHOOL OF MEDICINE: THE CHAIR OF PHYSIOLOGY —Dr. T Graham Brown, who since his release from military service has been carrying on his work as lecturer on experimental physiology at Manchester, has been appointed Professor of Physiology in the Welsh National School of Medicine, to the chair which fell vacant on the resignation of Professor J Berry Haycraft Professor Brown will be in charge of the new physiological laboratories recently erected at Cardiff

ENCEPHALITIS LETHARGICA

(EPIDEMIC ENCEPHALITIS).

BY EDWIN BRAMWELL, M.D., F.R.C.P. EDIN., F.R.C.P. LOND., F.R.S.E.,
PHYSICIAN TO THE EDINBURGH ROYAL INFIRMARY; LECTURER ON NEUROLOGY AND CLINICAL MEDICINE, EDINBURGH UNIVERSITY.

With a Note on

POST-MORTEM FINDINGS IN A SERIES OF CASES OF ENCEPHALITIS.

BY JAMES MILLER, M.D., F.R.C.P. EDIN.,
LECTURER ON MORBID ANATOMY, EDINBURGH UNIVERSITY.

THERE is an especial fascination to the clinician attaching to a disorder which presents no single distinctive feature, which may simulate, or be simulated by, a large number of other affections, and in the recognition of which cytological, bacteriological, and chemical procedures have hitherto failed to afford any positive assistance. I may remind you that in the spring of 1917 von Economo[5] directed attention to a "new disease," * cases of which were occurring in Vienna and its neighbourhood; that in the early spring of 1918 Netter[18] observed cases with a corresponding symptomatology in Paris; that in April of the same year Wilfred Harris[9] and Arthur J. Hall[7] simultaneously reported the presence in England of cases which presented similar features; and that Bassoe[1] was the first to report cases of the disease in the United States in March, 1919. No doubt you will remember the general interest evoked in the public press by the suggestion that these cases might be attributable to the *Bacillus botulinus*—a suggestion which was before long proved to be incorrect. Crookshank,[4] Melland,[16] Kinnier Wilson,[24] Farquhar Buzzard,[3] S. P. James,[10] James McIntosh,[12] A. S. MacNalty,[13] R. J. Reece,[20] and Marinesco,[15] among others in this country, have contributed to the literature; numerous isolated case records have been reported, and the subject has been discussed at several sectional meetings of the Royal Society of Medicine, while in October, 1918, a Blue-book, entitled "Encephalitis Lethargica—an Enquiry into an Obscure Disease," was issued by the Local Government Board. Nevertheless, I am satisfied that cases of encephalitis lethargica are only exceptionally recognised, and this is not surprising for several reasons. In the first place, the clinical pictures presented, even by typical cases, are very varied; again, a variety of different titles were employed with which to designate the earlier case reports; while, further, during 1918, when the majority of the contributions to the literature of encephalitis lethargica were appearing in the medical journals, practitioners had but little opportunity or leisure for literary study. This being so, I feel that no apology is called for as an introduction to the following remarks, which are based upon a considerable experience of the disease.

Evolution of Conception of Encephalitis.

As a preface to subsequent considerations, it is interesting to trace what I may term the steps in evolution, both eliminative and constructive, which have led up to the present-day pathological and clinical conceptions of non-suppurative encephalitis.

The current view regarding encephalitis in the early "forties" of last century may be illustrated by reference to a remarkable work, "The Diseases and Derangements of the Nervous System," published in 1841 by Marshall Hall, a name to be remembered as one of the most distinguished in the history of British neurology. This authority, under the term "encephalitis," included not only meningitis, abscess of the brain, and, indeed, all inflammatory processes within the cranium, but in addition the cerebral softenings, the relation of which to interference with the blood-supply was at that time not recognised. Although Marshall Hall enumerates a number of clinical features which are met with as a sequel to the various processes just mentioned, the latter were not differentiated pathologically, and a diagnosis during life was consequently impossible.

Three names stand pre-eminent in relation to the process of elimination which has led up to the present-day conception. Thus Virchow, who in 1846 published his famous work on embolism and thrombosis, may be said to have paved the way to the discovery that the great majority of the softenings of the brain substance, which had hitherto been attributed to an inflammatory process, were in reality a consequence of vascular occlusion. Again, Quincke, by the introduction of lumbar puncture in 1891, opened up a new field in the study of the cerebro-spinal fluid, and thereby effected a great advance in the diagnosis and differential diagnosis of meningitis; while Sir William Macewen, who in 1893 produced his well-known work upon "The Pyogenic Diseases of the Nervous System," has probably done more than any other observer to further our knowledge of suppurative encephalitis or abscess of the brain.

Constructive evolution dates from the early "eighties" of last century. Four groups of non-suppurative encephalitis have, I think I may say, been recognised by clinicians in the past, and to these I shall now briefly allude. Wernicke, in 1881, recorded three cases of encephalitis which were characterised clinically by an ophthalmoplegia of more or less sudden onset and pathologically by an acute hæmorrhagic inflammation of the grey matter of the floor of the third and fourth ventricles and in the neighbourhood of the aqueduct of Sylvius. Alcohol appeared to play a definite rôle in relation to these cases. Since the symptoms were purely motor, and since the process was an inflammatory one which affected essentially the motor nuclei in the upper part of the brain stem, Wernicke compared the condition which is now often known by his name to acute poliomyelitis, and termed it superior hæmorrhagic polioencephalitis. The adoption of this nomenclature was perhaps unfortunate, since the two disorders, although they present an homologous pathological anatomy, are ætiologically and clinically distinct. Wernicke's superior polioencephalitis has been, in the past at least, a condition of extreme rarity. Strümpell, in 1884, advanced the view that the cerebral palsies of childhood are for the most part dependent upon an encephalitis of the cortex of the brain, similar in its nature to the poliomyelitis of the spinal cord. Admitting the truth of the contention advanced by his critics that an inflammation limited to the cortex would not account for a widespread involvement of the white matter of the hemispheres with porencephaly, such as is observed in some of these cases, Strümpell abandoned the term polioencephalitis, which he had originally employed in this connexion, and in his later writings speaks of the encephalitis of childhood. There is reason for believing that the encephalitis of Strümpell may be due to a specific organism, the nature of which has not, however, as yet been determined. The same observer appears to have been the first to describe an encephalitis with a cerebral localisation in the adult. Medin, the Swedish physician, who at the Berlin meeting of the International Medical Congress in 1890 reported an outbreak of poliomyelitis in Stockholm, demonstrated that cerebral palsies are far from uncommon in epidemic poliomyelitis. The dependence of these symptoms upon an encephalitis, which must obviously be due to the same specific virus as poliomyelitis, has since been proved anatomically by Wickman and others. The occasional occurrence of an encephalitis as a sequel to one or other of the infective fevers is repeatedly referred to in the literature. It would seem, to judge by the number of infective maladies in the course of which an encephalitis has been noted, that a great variety of different organisms are capable of producing an inflammation of the brain, although the combination of circumstances which permits of this must be one of extreme rarity.

I shall now direct your attention to encephalitis lethargica †—the type of encephalitis which has been so prevalent of late—with particular reference to the clinical features these cases present and the many problems in diagnosis to which they give rise. I find that I have notes of 57 cases seen since March, 1918, in which I have made a definite diagnosis of encephalitis lethargica or epidemic encephalitis An opportunity of corroborating the diagnosis after death was, it is true, *only afforded on three occasions*, a circumstance accounted for by the fact that the great majority of the cases were seen in consulting practice, only four patients dying in hospital The series above referred to includes, however, no case in which the nature of the condition appeared to be open to reasonable doubt

---

* F. G. Crookshank[4a] has adduced evidence from the older medical literature, which suggests that epidemics of encephalitis have occurred from time to time during the past 450 years.

† The desirability of retaining the term "encephalitis lethargica," which was originally introduced by Economo[5] and adopted by the Local Government Board,[13] has been called in question. Kinnier Wilson[24] objects to the term on the ground that it is illegitimate to apply a clinical adjective to a pathological substantive. A. J. Hall advocates "sleeping palsy" for popular use, since it is less cumbersome and at the same time expressive, distinctive, and non-committal. Exception may, indeed, be taken to the adjective "lethargica," since lethargy, although a characteristic feature, is not perhaps a constant accompaniment of the pathological process. There are reasons for believing that lethargy may be a focal mid-brain manifestation, and it is quite possible that further pathological observation may demonstrate that the effects of the causal virus are at times confined to parts other than the brain stem. This being so, it would appear to the writer to be inexpedient in the present state of knowledge to attempt to supersede the current nomenclature by a clinical appellation which in the near future may perhaps be replaced with advantage by a more appropriate ætiological terminology.

The Characteristic Clinical Picture

The *mode of onset* varies As a rule, the symptoms develop gradually, and even in very severe cases it may be a few days or even a week or two before they become pronounced Amongst the prominent earliest symptoms I have observed are the following, viz Abnormal drowsiness, with a tendency to fall asleep when reading or working, diplopia, defective vision, consequent upon paresis of accommodation, a feeling of light headedness, some loss of emotional control, pronounced constipation; difficulty in passing urine, and severe peripheral pains simulating a localised neuritis In other cases no such prodromal period is observed The patient may go to bed feeling in his usual health and wake next morning presenting well marked manifestations of the disease Occasionally the onset is apoplectiform Thus, three of my patients fell suddenly to the ground unconscious A rise of temperature, usually accompanied by headache, an increase in the state of apathy, and sometimes vomiting, marks the true onset of the illness Exceptionally restlessness and, it may be, mental excitement are observed in place of the characteristic lethargy

A recognition of the various modes of onset is necessary in relation to early diagnosis I would recognise four groups of cases in this connexion —

(*a*) An asthenic or somnolent type, to which the great majority belong

(*b*) A meningitic type, to which A J Hall especially has drawn attention

(*c*) An apoplectiform type

(*d*) A neuralgic type which is characterised by very severe pain referred to one or more extremities or to the head.

A typical case of encephalitis lethargica presents a striking physiognomy

The patient usually lies on his back, the eyes half closed, the face may be flushed and covered with beads of perspiration (in three cases unilateral sweating and in two a conjunctivitis was observed) Often the patient will lie motionless for hours at a time without making any attempt to alter his position He makes no complaint, he appears to take no interest in his surroundings, and yet there may be only a moderate degree of somnolence Again, in other cases the patient, though oblivious to his surroundings, is in a restless state, he mutters to himself or talks aloud He is evidently disorientated, for his delirium refers to his daily occupation Thus, one of my patients, a sergeant was constantly drilling his men, another, a lawyer, giving instructions to his clerks, and a third, a business man, carrying on animated conversations by telephone The lips are seen to move, and yet the face is often strikingly immobile and expressionless There may, however, be some tremor and occasionally spasmodic twitchings of the facial muscles From time to time the patient fumbles with the bedclothes, and an irregular tremor or spasmodic jerkings of the limbs may then be noticeable The general appearance may, indeed, closely resemble that of a case of delirium tremens Although the patient may appear to be in a state of semi-stupor, he will often when addressed, awake from his somnolent condition or break off in the middle of his delirium and reply intelligently to questions put to him, although his responses are slow, his intonation monotonous, and his articulation often somewhat indistinct In two cases a complete disorientation, both as regards time and space, was noted Pains in the limbs, when any attempt is made to move the patient are not uncommonly complained of Variations in the lethargic state, from a slight degree of somnolence to actual coma in severe cases may be observed from time to time Paradoxical as it may seem, sleeplessness is not infrequent When the stupor is pronounced loss of control over the sphincters and difficulty in swallowing are observed

Upon examination the temperature will generally be found to be slightly elevated if the patient is seen within the first few days of his illness (in my experience the temperature rarely rises above 101 or 102° unless towards the termination of a fatal case) The temperature usually falls in a few days, although it may remain elevated for two or three weeks after which it is commonly subnormal Exceptionally a slight rise of temperature, persisting for a day or two, is observed at a later date The pulse rate is somewhat accelerated and not infrequently out of proportion to the febrile disturbance The tongue is usually very dry, and it may be coated A moderate degree of neck rigidity, together with Kernig's sign, may be present, though both these phenomena are exceptional In two or three cases I have observed a diffuse erythema and in one case herpes labialis

Focal nervous symptoms referable to the ocular muscles are of very frequent occurrence Thus, bilateral ptosis a divergent strabismus, some defect of the ocular movements, notably a paresis of the muscles supplied by the third nerves, nystagmus, inequality of the pupils, which may be widely dilated and usually respond sluggishly to light, and paresis of the ciliary muscles with consequent impairment of vision due to defective accommodation, are often observed Not infrequently, too, there is some paresis of the facial muscles, as a rule, though not always, bilateral, and amounting sometimes to a complete paralysis Generalised weakness of the limbs, more accurately described as a profound asthenia than a paralysis, is the rule Sometimes, however, a definite mono or hemi paresis is present Katatonia is a common symptom when the somnolence is pronounced The knee jerks show no constant alteration, they may be exaggerated, while occasionally they are absent The plantar reflexes are usually of the flexor type, though exceptionally an extensor response can be elicited Changes in the fundus oculi are seldom met with although in several cases I have seen engorgement of the veins, and in two cases in which the diagnosis was not absolutely certain, and which are not included in this series, an optic neuritis was present I have met with no case in which there was a history of a fit One patient exhibited pronounced maniacal excitement Upon lumbar puncture a clear cerebro spinal fluid, which is not under pressure, but which may contain a slight excess of cellular elements of the lymphocyte type is usually obtained In two cases of probable encephalitis lethargica, not included in this series, altered blood was withdrawn on lumbar puncture As to the blood my observations are in accord with those of Vaidya and of William Boyd[2a] that a leucocytosis is exceptional and, when present, of slight degree, while in four of my cases in which differential counts were made no definite abnormality was detected In two cases sugar and in one case albumin and blood were present in the urine Enlargement of the spleen was observed in no instance Catarrhal symptoms referable to the respiratory tract are, in my experience, unusual, they certainly do not occupy a prominent place in the clinical picture

Salient Clinical Features

The salient clinical features of the common type of encephalitis lethargica may be conveniently classed in three groups as follows —

(1) *Febrile disturbance which is met with almost invariably in the initial stages Although as a rule slight in degree and consequently apt to escape detection, this symptom is important in relation to diagnosis Accompanying the fever certain general symptoms, such as headache and, less commonly, giddiness and vomiting, are often met with during the earlier days of the illness*

(2) *A state of progressive somnolence apathy and lethargy, from which the affection derives its appropriate designation This symptom, which is present in the great majority of cases is associated with slow mental action, want of initiative and when pronounced, as a rule, with an occupational delirium*

(3) Symptoms referable to focal disturbances in the function of the nervous system, a consequence of the structural changes produced by the morbid process These vary according to the region of the nervous system in which the lesion is situated or most pronounced The frequency with which paresis of the ocular muscles notably of those supplied by the third nerves (ptosis, strabismus, defective movements of the eyes, nystagmus, unequal and sluggish pupils, and defective accommodation), and paresis of the face are met with is explained by the fact that in the majority of cases the mesencephalon and pons are the special regions selected by the process

Before proceeding to refer to exceptional types and to allude to certain problems of differential diagnosis I would emphasise two points In the first place, let me again remind you of the various modes of onset to which I have referred and the early premonitory symptoms met with in certain cases, while, secondly, it is necessary that you should realise that, although the focal nervous symptoms commonly make their appearance in the initial stages of the illness, they sometimes continue to develop for two or three weeks, in other words, the local lesion may be progressive

Diagnosis.

The above description is applicable to pronounced cases of what may be termed the characteristic mesencephalic type of the disease. All cases, however, do not present such a symptomatology; indeed, I know of no affection which manifests such a multiplicity of clinical pictures, and, consequently, offers so many difficulties in diagnosis. The symptomatology varies according to the mode of onset, the preponderance of general or focal manifestations, and the region of the brain affected by the lesion. Since encephalitis lethargica may closely resemble a number of different conditions, since no single symptom can be regarded as pathognomonic, and since pathological methods afford no help of a positive kind in its recognition, diagnosis by exclusion necessarily plays a prominent rôle, and the physician's general experience and clinical acumen may consequently be severely taxed.

As an aid to diagnosis it is convenient, as suggested by MacNalty[13] in his excellent article, to recognise a number of clinical types, among which the following are illustrated by cases which have come under my observation.

(1) The common or mesencephalic type, to which the great majority of cases belong. This type is characterised, as has been mentioned, by febrile disturbance and by a state of apathy, somnolence, general lethargy, or even stupor, associated with paresis of the ocular and facial musculature. The diagnosis here presents little difficulty.

(2) A type in which the lethargy, somnolence, and sometimes symptoms of meningeal infection are pronounced, while focal nervous symptoms are either inconspicuous or absent. Cases of this kind are by no means infrequent. They are apt to be mistaken for a variety of other conditions, among which I would especially mention the following, which I have known to give rise to difficulty in diagnosis, viz.: cerebro-spinal fever, tuberculous meningitis, influenza, typhoid fever, cerebral arterio-sclerosis, and uræmia.

(3) Cases which present striking focal symptoms referable to the mesencephalon (ophthalmoplegia, facial paralysis, &c.), though the initial febrile disturbance has been so slight and evanescent that it has escaped notice, and the somnolence and lethargy are inconspicuous and overshadowed by the focal manifestations. In three cases of the kind which I have met with a diagnosis of intracranial tumour had been previously advanced by a competent observer. It is, indeed, very probable, as Nonne has suggested, that some of the reported instances of supposed intracranial neoplasm, in which the growth of the tumour had apparently become arrested, have been cases of encephalitis.

(4) An abortive type, illustrated by one of my cases, in which the symptoms, never pronounced, pass off more or less completely in the course of two or three weeks.

(5) A type which closely resembles paralysis agitans. The similarity which some cases of encephalitis lethargica present to paralysis agitans has been emphasised by Farquhar Buzzard.[8] Several such cases have come under my notice. The resemblance was particularly striking in the case of one patient, in whom the expressionless face, the monotonous voice, attitude and gait so closely resembled Parkinson's disease that, had no history of the illness been available, it would have been difficult to differentiate between the two conditions. In another case, a rhythmic tremor confined to one arm presented features indistinguishable from that of paralysis agitans, while the immobility of the face emphasised the similarity. Here, again, a history of a febrile onset with diplopia, together with the subsequent course of the illness, placed the diagnosis beyond question. No doubt the phenomena met with in this type of the disease are to be explained by implication of the red nucleus or rubro-spinal tract.

(6) Cerebellar ataxia was a striking feature in one case in which the symptoms suggested the possibility of disseminated sclerosis, an alternative diagnosis which in two other instances was only dismissed after full consideration of all the facts. In a second case in which recovery was eventually complete, the association of cerebellar symptoms, with somewhat severe headache and vomiting, raised the question of a tumour in this region of the brain.

(7) Progressive focal symptoms referable to the motor nuclei of the lower cranial nerves in the medulla, and unaccompanied by any general manifestations, were observed in one case in which the diagnosis between tumour and encephalitis remained doubtful until eventually determined by post-mortem examination. In distinguishing between tumour and encephalitis I would in passing remind you that the difficulty is accentuated by the fact that neoplasms situated in the brain stem are often unaccompanied by indications of increased intracranial pressure (headache, vomiting, and optic neuritis), while, further, the focal nervous symptoms in encephalitis lethargica may be progressive.

(8) A cerebral localisation was observed in three cases; in two of these hemiplegic symptoms, in the third a monoplegia, were, in my opinion, dependent upon an encephalitis. The diagnosis in two of these cases was based on the fact that there was a history of a definite febrile onset with ocular palsies, while in none of the three were there indications pointing to any other factor which might account for the paralysis. Recovery was complete in all, a fact which afforded corroborative evidence as to their nature.

When one remembers that encephalitis lethargica may commence with the suddenness of an apoplexy, as I have personally seen on three occasions, the difficulty in differentiating cases of the kind from cerebral hæmorrhage or occlusion of the cerebral vessels is at once apparent. The absence of signs of cardio-vascular disease and the exclusion of syphilis are matters of importance in this connexion, while the rarity of hæmorrhage into a glioma which has previously given rise to no symptoms renders such a possibility unlikely. Farquhar Buzzard[8] has described cases with hæmorrhage on the surface of the brain. Attention has been drawn to the fact that emotional disturbance is not infrequently observed in cases of encephalitis lethargica. In the absence of fever or of certain indications of an organic process an erroneous diagnosis of functional disease can be understood. I made this mistake in one case in which the temperature, which was normal at the time of my examination, rose two days later; the patient died within a week from symptoms which appeared to be undoubtedly due to an encephalitis.

The above remarks will serve to indicate the protean symptomatology of encephalitis lethargica and at the same time to illustrate some of the numerous difficulties which may arise in the diagnosis of this disease. A case may, indeed, present very different features, and consequently raise very different diagnostic problems, according as it is seen during the prodromal stage, in the febrile period, or at a later date when the general symptoms have largely passed off. In the great majority of the cases I have seen encephalitis lethargica had not been previously suspected. Time and again a practitioner, when asking me to see a patient, has told me that he was quite at a loss as to the diagnosis, since the case I was to see presented features he had never previously met with.

Pathological Features.

Anatomical observation demonstrates that the affection under discussion is dependent upon an encephalitis which shows a special, though not invariable, predilection for the brain stem. Since Dr. James Miller will review the morbid anatomy of the disease and narrate his personal observations, I do not propose to refer to this aspect of the subject. At the same time I should like in passing to make a brief reference to the correlation of the morbid anatomy and symptomatic features. Let me draw your attention more particularly in this connexion to the infiltration of the tissues, and particularly to the infiltration of the walls of the blood-vessels in the affected region with cells of the lymphocyte type, to the œdema of the brain substance, to the small hæmorrhages which are occasionally observed, and to the neuroglial proliferation which is met with here and there.

The histological characters of the lesion indicate its infective nature and afford an adequate explanation of the associated febrile disturbance, while its distribution and anatomical features account for the frequently bilateral, though often asymmetrical, and usually incomplete, character of the pareses, the occasional variation in the intensity of the symptoms, and the fact that although in some cases the patient makes a complete recovery in others some permanent disability persists. The circumstance that the anatomical changes are confined to the mesencephalon and pons, or are, at any rate, usually more intense in these regions, is only what might be expected in view of the focal nervous symptoms which are most commonly met with.

The paresis of the oculo motor, of the facial, and, it may be, of other cranial nerves, is evidently due to involvement either of their respective nuclei or of their nerve fibres as they traverse the substance of the brain Nystagmus, which is so frequent, may be accounted for by interference with the function of the direct nerve supply to the ocular muscles or to implication of the posterior longitudinal bundle The not infrequent mask like face and the tremor, which is sometimes met with, are doubtless to be explained by interference with the function of the red nucleus or rubro spinal tract Again, the cerebellar ataxia observed in two of my cases may be accounted for by implication of the cerebellar peduncles or the cerebellum itself, while the general asthenia may be explained by involvement of the motor nuclei in the spinal cord (?) It may be that the pains in the limbs and the tenderness of the muscles sometimes complained of are dependent upon changes in the peripheral nerves, although no pathological observations have so far been recorded in proof of this suggestion Babinski's sign when present, and exaggeration of the knee jerks are obviously a consequence of interference with the efferent cortico spinal tracts

The mode of production of the lethargic state is less apparent

Since headache is rarely severe and vomiting, when it occurs, is a transient symptom, since optic neuritis is seldom, if ever, met with, and since the cerebro spinal fluid is not under pressure, it would seem that the state of lethargy is probably not dependent upon a general increase of intracranial pressure—a conclusion which is supported by post mortem evidence Again, a study of the literature would seem to indicate that generalised œdema of the brain is not a pronounced or constant feature The question consequently arises, May the lethargic state possibly be explained by the focal lesion in the brain stem? The optic thalamus, as is well known, constitutes a receptive centre for all afferent stimuli, and the view has been advocated by MacNalty[13] that the lethargic state may be due to an interruption of the afferent stimuli passing to the thalamus This hypothesis is an attractive one The circumstances that in both sleeping sickness and basal syphilis perivascular infiltration is a prominent feature, and that in the former drowsiness is a constant, in the latter a not infrequent, symptom, are, I think, suggestive in this connexion Further, I have seen more than one case in which I diagnosed an encephalitis of the cerebrum in which drowsiness was not, at any rate, a striking feature

The specific cause of encephalitis is as yet unknown

Von Wiesner,[23] working in association with von Economo, affirmed in 1917 that he had discovered a diplostreptococcus to which he attributed specific properties This author's contentions have, however, been criticised by Kinnier Wilson[21] and others, and his deductions have not been accepted as conclusive The careful bacteriological observations of McIntosh[12] were of a negative character Marinesco,[15] and da Fano and Ingleby[6] have described intracellular bodies which may possibly be of an organismal nature but their observations demand further corroboration James Miller investigated bacteriologically the cerebro spinal fluid blood, fæces, urine, and pharyngeal secretion in four of my cases, with a negative result in so far as he found no pathogenic organisms Animal experiments carried out by McIntosh[13] and others have been of a negative kind Recently, however, Strauss, Loewe and Hirshfeld[21] have affirmed that they have succeeded in producing an encephalitis experimentally It has been suggested that the causal organism may obtain access by the nasal mucous membrane One of my cases was of special interest in this connexion, for the encephalitis developed while the patient was in hospital a few days after the removal of a nasal polypus This man, who stated that he had had a purulent discharge from the nose for some time previously, was it is interesting to note, proved by Dr Miller to be a meningococcal carrier

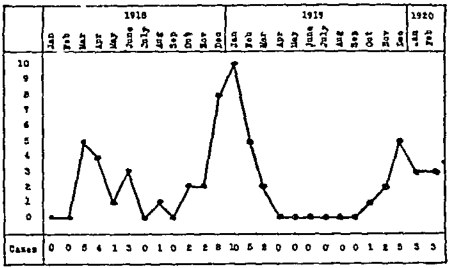
General Ætiological Considerations

Although no cases of encephalitis lethargica have, so far as I am aware, been hitherto reported from Scotland, my experience suggests that the disease has probably been as prevalent north of the Tweed as in England and Wales This statement is supported by figures extracted from the mortality returns from Scotland for the first three months of 1919, which Dr J. C Dunlop, the Superintendent of Statistics, has kindly placed at my disposal

According to these figures, "The total number of deaths certified as due to encephalitis during the first quarter of the year 1919 was 58, in the corresponding quarter of 1918 the number was 11, in that of 1917, 14, in 1916, 20, and in 1915, 9" While it is to be remembered that a number of different conditions are included under the term "encephalitis," the figures are at least significant In 17 of the 57 cases I have met with the patients were living in Edinburgh when the first symptom appeared, while, with four exceptions, the others were residing in a town Two patients were attacked while on board ship, one, a soldier, was in camp, while one patient was living in a somewhat isolated farmhouse in the country This experience is of interest, since R J Reece,[20] from an analysis of the cases of encephalitis lethargica occurring in England and Wales during the first quarter of 1919 during which period notification was compulsory, finds the proportion of urban cases to cases occurring in rural districts in terms of the population 9 4 to 4 9

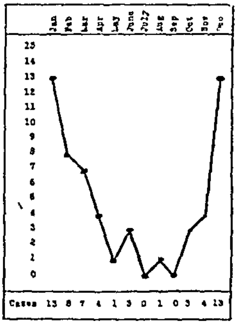
The sexes appear to be about equally liable Thus, 29 of my patients were males, 28 females, of the latter, 14 were married The average age of the males at the time of onset was 43, that of the females 35 The youngest patient in the series was 17, the oldest 75 Reece's statistics, however, show that a number of cases have been notified in children and even in infants Although Batten and Still[2] described four cases of "epidemic stupor in children" so long ago as May, 1918, there appears to be good reason for believing that encephalitis lethargica is very rare in early childhood Since 41 of my patients were seen in consulting practice, 10 in civil, and 6 in military hospital practice, it would seem that encephalitis lethargica is at least as common among the middle as among the lower classes The majority of the patients I have seen had been apparently in good health previously, Bassoe,[1] however, states that nearly all his patients had been in a more or less run down condition prior to the onset Instances of more than one case in a family, though very unusual, have been reported by Harris,[9] Farquhar Buzzard, and MacNalty,[14] while Reece[20] has met with a case of a nurse who contracted the illness while attending a patient suffering from the disease My experience indicates that syphilis, alcohol, and trauma appear to play no part in the causation of encephalitis lethargica

CHART I



Date of onset in 57 cases of encephalitis lethargica

CHART II



Month of onset in 57 cases of encephalitis lethargica

Seasonal Incidence.

Dr S P James,[10] in discussing the epidemiology of encephalitis lethargica with reference to the earlier cases observed in the spring of 1918, states "Most of the cases reported occurred during the seven weeks between the 16th March and 4th May and according to the figures, the disease reached its maximum prevalence somewhat slowly, maintaining its prevalence for a comparatively brief period and gradually declining" This authority is of opinion that the numbers of cases at that time reported were less an index of the seasonal prevalence of a new disease than they were the index of the rise and decline of activity in discovering and reporting cases of an old one Since the above remarks were made no evidence so far as I am aware, has been published which either supports or confutes the question of a seasonal incidence in relation to this disease My own experience, although I admit the number of cases (57) is perhaps too small to justify definite conclusions, affords, I think, suggestive evidence in this connexion. I would draw attention to the following points which are illustrated in the accompanying figure. Firstly, in 5 of my cases the symptoms developed during March, 1918. Secondly, I met with but few cases which developed during the summer months of 1918. Thirdly, in no less than 23 cases the illness commenced during December, 1918, and January and February, 1919. Fourthly, I did not meet with a single case in which the date of onset was between April and September, 1919, although, it is true, Dr. Byrom Bramwell observed 3 cases during this period. Fifthly, during the past three months I have observed 11 cases. These figures seem to indicate that there is a tendency for encephalitis lethargica to occur during the colder months of the year.

Botulism, Poliomyelitis, and Influenza.

When the earlier cases of encephalitis lethargica were reported in this country the suggestion was advanced that the condition might be botulism. I am indebted for my knowledge of this condition to Dickson's monograph.

The term botulism is applied to a type of food poisoning which results from the ingestion of sausages, tinned beans, and other articles of diet contaminated with the *Bacillus botulinus*. Outbreaks of this type of food poisoning have been reported from time to time for many years past in various parts of Germany and Austria-Hungary, as also in Denmark, America, and elsewhere. A group of cases was, indeed, described in England in 1860. The symptoms of botulism evidently bear a close resemblance to those of encephalitis lethargica. Thus, in both ophthalmoplegia, general muscular feebleness, defective salivary secretion, constipation, retention of urine, and difficulty in swallowing are common features. On the other hand, botulism is preceded by gastro-intestinal symptoms, there is no febrile disturbance, the cases occur in groups, and their origin can be traced to a food product, while the *Bacillus botulinus* of van Ermengem is, it is affirmed, readily detected in the stools.

Acute poliomyelitis is another disorder which presents points of similarity to encephalitis lethargica, and it has been suggested that the latter disease may be due to a modification of the virus which is responsible for the former.

The two affections resemble each other in that both are dependent upon an infective process, and in both the causative agent attacks the central nervous system; while, further, the sporadic manner in which cases of both disorders crop up throughout the country is very similar. There are, however, strong arguments which are opposed to the view that the resemblance is more than superficial. Thus, I have met with no cases of encephalitis lethargica which presented a localised flaccid palsy such as one meets with in poliomyelitis. Again, when some years ago poliomyelitis was comparatively frequent throughout the country cases of encephalitis lethargica were not observed. Further, according to Reece,[20] poliomyelitis showed no increase throughout England and Wales in the first three months of 1919, though encephalitis lethargica was prevalent. Again, the age incidence is different, poliomyelitis being essentially a disease of children and young adults, while encephalitis lethargica is much more frequent in adult age. Lastly, poliomyelitis occurs especially in the late summer and autumn, while the evidence I have adduced suggests that encephalitis lethargica is met with during the colder months of the year. I might mention other points of difference, but those I have noted are, I think, sufficient to show that the two affections are in many respects dissimilar.

Influenza has of late been rife throughout the country, and the question arises whether the disease under consideration may be due to the virus of influenza, and if this is not the case whether there is any relationship between the two conditions.

It is noteworthy in this connexion that a number of cases of encephalitis were recorded by Leichtenstern[11] and other German writers at the time of, and subsequent to, the great influenza epidemic of 1889-90, and that about the same time a peculiar disease termed "Nona,"[1] which was characterised by pronounced drowsiness, was very prevalent in Austria and Northern Italy. Nauwerck,[17] in 1893, discovered the Pfeiffer bacillus in the brain of a fatal case of encephalitis, and Cantani, three years later, succeeded in producing an encephalitis experimentally in rabbits by injecting a dead culture of the influenza organism. These facts are very suggestive, and Oppenheim and Cassirer,[10] in their monograph upon encephalitis published in 1907, describe an influenzal type of encephalitis which, to judge from their description, is so very similar as to be almost indistinguishable from encephalitis lethargica. That an encephalitis may occur in the course of influenza just as it does very exceptionally in the course of a great variety of infective disorders is highly probable, but the available facts do not, in my opinion, justify the conclusion that epidemic encephalitis, which is almost certainly due to a specific infection, is dependent upon the same virus as influenza. The following observations are of interest in this relation. Firstly, in no single instance among the cases of encephalitis I have met with, in which the patient was living in a private house, were there cases of influenza in the family. Secondly, I have observed no case of encephalitis in which there was evidence of infection from person to person. Thirdly, with a few (? two or three) possible exceptions, in no instance was the illness ushered in by catarrhal symptoms, prostrating frontal headache, or severe pain in the back and limbs such as are recognised to be common clinical features in many influenza epidemics. Fourthly, with very few exceptions, a history of a recent attack of influenza was not forthcoming. Fifthly, during the past three months, while there has been comparatively little influenza in Edinburgh or its neighbourhood, cases of encephalitis have not been infrequent. Finally, the circumstance that two infective disorders are epidemic at the same time is no proof that they are dependent upon the same infection. It may well be that common predisposing factors exist which, by lowering the general resistance, determine their simultaneous incidence.

Prognosis.

The mortality in encephalitis lethargica varies considerably, to judge by the recorded experience of different observers.

Thus, 6 cases of 11 reported by Economo, 7 of Netter's 15 cases, 2 of Wilson's 13 cases, and none of Hall's[8] 16 cases died, while 9 of the 57 cases I have observed terminated fatally. The mortality among 126 cases collected by the Local Government Board in 1918 was 20 per cent.; while of the 61 cases observed in the Winnipeg epidemic more than a third died. According to Netter, death may be due to an extension of the encephalitis to the medulla, to pneumonia secondary to paralysis of the vagus or glosso-laryngeal, or to general wasting complicated by bedsores. The ages at death of the seven patients included in my series were as follows: 17, 18, 24, 27, 32, 42, 45, 47, and 60. Five of my patients died between the eighteenth and twenty-second day after the onset of symptoms, one patient dying on the seventh day, another during the fourth week. In this connexion it is of interest to note that the average duration of the illness in the 25 fatal cases collected by the Local Government Board was 21 days, the shortest being 6, the longest 49 days.

My experience does not justify me in formulating any very definite conclusions in relation to prognosis. The circumstance that the three patients in whom the onset was apoplectiform made a good recovery, as did all the patients (4) in whom pronounced meningitic symptoms were a prominent feature in the early stages, is of interest, but may be explained by coincidence. In three of my nine fatal cases, all of which presented a mesencephalic localisation, the general symptoms were pronounced and the focal manifestations comparatively insignificant. If the patient survives the first three weeks of his illness the probabilities are all in favour of recovery. A high temperature, pronounced and deepening stupor, with accompanying dysphagia, and loss of sphincter control are symptoms of serious moment, though not necessarily indicative of a fatal termination.

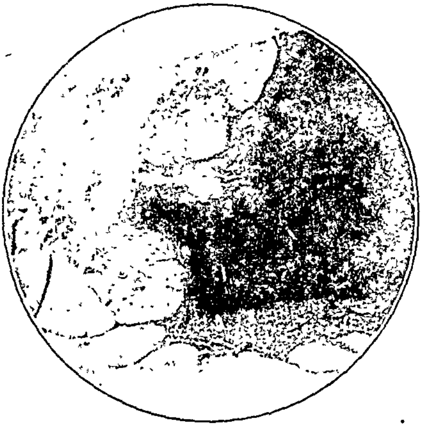
Improvement is almost always slow in those cases which eventually recover. The patient may remain for weeks or even months in a state of semi-stupor. On the other hand, abortive cases are met with, and are very possibly much more frequent than my experience suggests, in which recovery is practically complete after two or three weeks. Sometimes the general phenomena pass off in a few weeks, leaving merely focal symptoms, which may be very persistent. Complete, or practically complete, recovery was the rule in the majority of the cases I have met with. In several, however, such symptoms as general weakness, slow mental action, and defective concentration, want of initiative, giddiness, defective vision, sluggish pupils, and ocular pareses with diplopia still persist and will probably prove to be permanent. Hall[8] states that recovery was complete and absolute in seven of his cases; practically complete in six cases, some slight trace of illness being left behind; while three cases, after six months, were still far from recovery. I am inclined to think from my experience that the longer the state of somnolence or stupor persists the more likely are the focal nerve symptoms to be permanent. Buzzard and Greenfield point out that some time after the patient has recovered from the original illness a relapse characterised by involuntary movements may occur. I have observed two instances of the kind.

Treatment.

No therapeutic means have so far been proved to have an undoubtedly beneficial effect upon the course of the disease. A specific remedy has yet to be discovered.

Obstinate constipation is the rule in the early stages, and the use of calomel and other purgatives has been advocated for its relief. I am inclined, too, to think that I have seen improvement in the general lethargic state as a sequel to a loose movement of the bowels. Hexamin in doses of 10 gr. four-hourly was administered in most of the cases I have seen during the first days of the illness, but whether any definite beneficial result was thereby effected I am not prepared to say. Three cases which were under my care in hospital for a period of several weeks afforded opportunity for observing the effects of remedies. Since in sleeping sickness and syphilis of the cerebral vessels a state of somnolence or stupor is observed, and since both these affections are characterised pathologically by a perivascular infiltration, the possibility that iodides or arsenic might prove beneficial suggested itself. Anticipations were, however, not fulfilled, for these drugs, given in full doses, produced no definite improvement. Netter[18a] states that he has seen disastrous results follow the use of neosalvarsan, while he has seen no beneficial effect produced by antimony. Strychnine administered hypodermically in increasing doses up to a twelfth of a grain appeared to me to be of undoubted benefit in more than one case in which the state of somnolence was unduly prolonged. In one case I was rather inclined to think that quinine was of some service. Netter[18a] is of opinion that he has seen benefit follow the production of a local abscess by the injection of 1 or 2 cm. of turpentine into the thigh.

FIG. 1.



Large hæmorrhage in the substance of the cerebellum near the surface. Numerous minute hæmorrhages

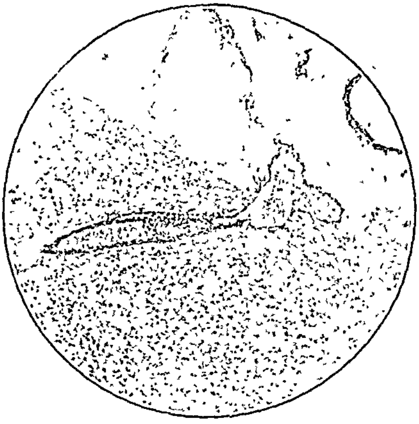
Note on Post-mortem Findings.

The material forming the basis of the pathological inquiry consisted of five fatal cases at the Edinburgh City Hospital and Royal Infirmary.

Morbid anatomy.—As McIntosh observes,‡ as a rule the autopsies in encephalitis cases are negative; in other words, no macroscopic changes sufficient to account for death are present. In one of the cases which died in the City Hospital in March, 1919, there was a well-marked purulent bronchitis and broncho-pneumonia, but as similar appearances were found in cases dying of "influenza" about that time no great stress could be laid upon the observation. In another case, which was under the charge of Dr. Chalmers Watson, a surface hæmorrhage was observed in the cerebellum measuring ½ inch across, with extravasation of blood under the pia arachnoid at the base of the brain. (Fig. 1.) A similar case is recorded by McIntosh, so that in cases of so-called meningeal hæmorrhage the possibility must be borne in mind that one is dealing with encephalitis lethargica. In all the five cases the surface vessels of the brain were injected, and on section the grey matter of the brain, cerebellum, and cord were unusually dark. There was some excess of cerebro-spinal fluid at the base of the brain. This fluid was clear and there was no exudate or opacity about the meninges. With the exception of the large hæmorrhage and some smaller ones in the neighbourhood in the case already mentioned, no extravasations were found in the brain substance, although a dilated vessel often gave the appearance of such. In one of the cases, a cyst, the size of a walnut, was present at the tip of the left temporo-sphenoidal lobe.

Microscopic appearances.—In each case the chief changes were met with in the pons and neighbouring portions of the mid-brain. In one instance the changes extended into the cervical cord, but the cerebellum (with the exception of the case already mentioned) and the cerebral cortex were relatively free. In relation to the distribution of the disease in the central nervous system the question arises as to what is to be regarded as the most characteristic lesion. In my experience little reliance can be placed upon the chromatolytic changes in this respect. The ravages of post-mortem change and the frequent coincident toxic effects on the ganglion cells render chromatolysis as a criterion for the extent of the disease most unreliable. Œdema, again, although a striking change in certain situations, is often ill-defined and spreads beyond the area of brain associated with clinical symptoms. A much more sure guide to the actual degree of irritation is the perivascular infiltration. This change, although not an indication of such profound and permanent alteration as the proliferation of the neuroglia or hæmorrhage, is probably the best guide to the extent of the affected nervous tissue.

FIG. 2.



Section of mesencephalon close to surface, showing how in encephalitis a meningeal vessel acquires the sheath of inflammatory cells only after penetrating the brain substance.

Changes in the nerve cells.—As already stated, the disturbances in the Nissl spindles and nuclei of the nerve cells are, in view of concomitant post-mortem and toxic changes, neither striking nor uniform. They certainly occur, as is evidenced by the loss of staining of the Nissl bodies and pale staining of the nucleus (although the nucleolus, as a rule, stains well), but the more advanced changes of disappearance or extrusion of the nucleus seldom occur. Moreover, these changes may not be met with in very striking degree in the cells of nuclei of nerves which are clinically affected. These degenerative changes in nerve cells are widely distributed. They occur not only in the mid-brain nuclei but in the grey matter of the cord and cerebellum. Marinesco, describing two cases of the disease,§ lays special stress upon changes in the Purkinje cells of the cerebellum. He speaks of them being profound. Da Fano and Ingleby also refer to nerve cell changes of a chromatolytic nature as being severe and widespread. In my series of cases no such striking changes were seen. I agree with McIntosh (loc. cit.) when he states that "in no instance was there that complete absence or destruction of the ganglion cells which occurs in the spinal cord in poliomyelitis."

Perivascular infiltration.—Certainly the most arresting microscopic change is the presence in large numbers of round cells in the perivascular lymph sheath of the vessels which have entered the brain substance. In my experience the vessels of the meninges are not affected in this way. Indeed, it is quite striking to observe the sudden appearance of the casing of cells as the vessel passes from the pia arachnoid into the cerebral tissue. (Fig. 2.) Outside, even in sulci and depressions, there is little evidence of cellular infiltration of the meninges. This is apparently in contrast to the observations of Loewe, Hirschfeld and Strauss ¶ in encephalitis experimentally produced in monkeys and rabbits. In one of my cases the perivascular infiltration was clearly seen in sections of the lower cervical region of the cord.

‡ Reports to the Local Government Board, New Series, No. 121.

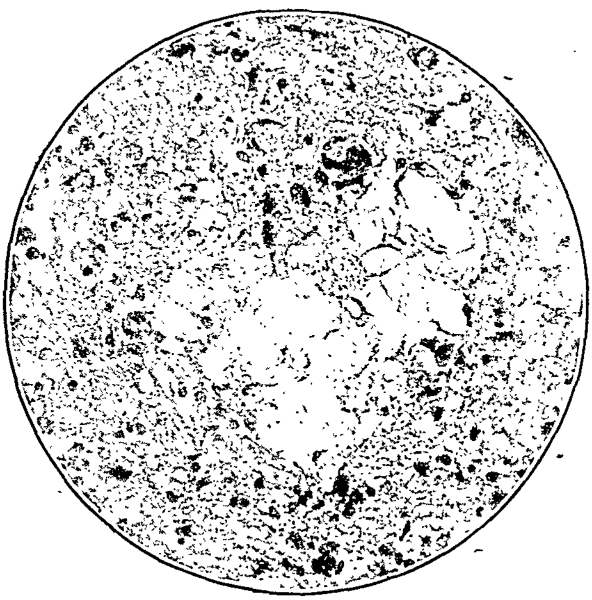
§ Ibid.

Proceedings of the Royal Society of Medicine, 1919, vol. xii., Section of Pathology, p. 42.

As regards the nature of the cells taking part in this infiltration, a majority appear to me to be lymphocytes or cells indistinguishable from such. McIntosh differentiates a certain number of polyblasts of Maximow and plasma cells. Marinesco describes fibroblasts, and in certain situations eosinophils. I have seen polymorphonuclear leucocytes in considerable numbers in one case.

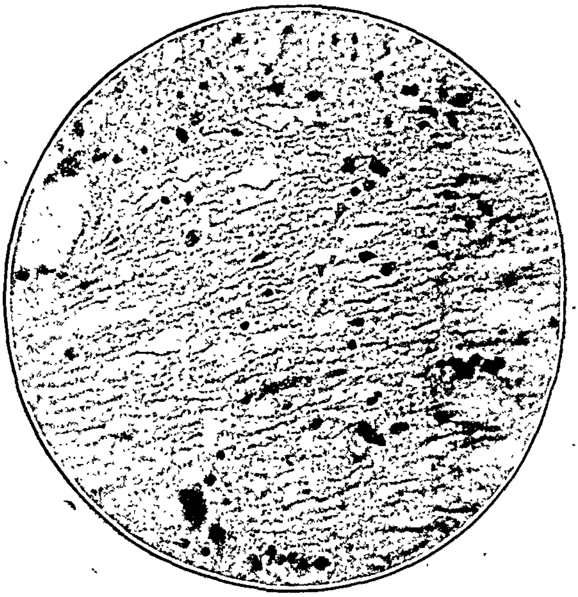
Œdema.—This is a term which, when applied to the central nervous system, is a little apt to be loosely used. Dilatation of the perivascular lymph space may be artificially produced by imperfect fixation. This change is, however, too constantly present and striking in encephalitis to be of the nature of an artefact. In addition to this, often widespread, manifestation of œdema there is an interstitial dropsy of a more significant type. In my series of cases it has been a striking feature of parts related to the third nucleus and its fibres as they leave the pons. (Fig. 4.) The initial change is a bubble-like clear space which appears in the substance of the pons separating the nerve elements from one another and extending often in a longitudinal fashion for some distance. This spread is particularly well seen along the course of the third nerve before it leaves the pons, resulting in a splitting and separation of the fibres from one another. The same change is also well seen in the substantia nigra (Fig. 3).

FIG. 3.



Section of mesencephalon showing interstitial œdema of substantia nigra. There is also scattering of the normal pigment.

FIG. 4.



Œdema of the fibres of the third nerve before its exit from the mesencephalon.

Hæmorrhage.—The frequency of hæmorrhage is perhaps exaggerated. This is probably more characteristic of poliomyelitis than of encephalitis. It shows itself first, as a rule, in the perivascular lymph space. This space, instead of being empty or containing round cells, is filled with red blood corpuscles. Less frequently these hæmorrhages occur into the cerebral substance, and occasionally, as already mentioned, they occur on the surface of the brain. In my series of cases, except in one instance, hæmorrhage was not a conspicuous feature. In this case there were numerous hæmorrhages, one of them large, into the substance of the cerebellum close to the surface. The blood extended along the subarachnoid space for some distance and blood was present in the cerebro-spinal fluid. Hæmorrhages of this type no doubt account for the occasional occurrence of a blood-stained fluid obtained by lumbar puncture.

Pigmentation.—This appears to have been a striking feature of the cases studied by Da Fano and Ingleby. These observers found the pigment in nerve cells both near and at a distance from points of cell infiltration. In my series of cases I found little evidence of such pigmentation. It was present in the cells of the fourth nucleus in one instance, but I saw no evidence at all of the other "granules" described by Da Fano and Ingleby. Many of my sections were stained by Leishman's method, but I failed to observe the bluish-white corpuscles, oval or rounded in form, seen by the same observers. Apparently Da Fano and Ingleby (loc. cit.) relate the pigment granules and corpuscles to one another, suggesting that they may be of the nature of a causal germ.

An interesting alteration in the distribution of the pigment of the substantia nigra was a striking feature of all my cases. The pigment, instead of being confined to the nerve cells themselves, was scattered in rounded masses in the surrounding tissues, both free and inside phagocytic cells (Fig. 3). There was at the same time a proliferation of the neuroglia cells in the neighbourhood, the pigment being largely contained in the proliferated neuroglia cells. Not infrequently these cells, as Marinesco points out, contain several nuclei.

Summing up the histological changes I would give chief place to: (1) Hæmorrhage (a rare occurrence in my series of cases); (2) œdema of the nerve tissue; (3) proliferation of neuroglia; and (4) infiltration of nerve tissue and perivascular lymph sheath with cells, usually lymphocyte-like in type. In the cases which I have examined these changes are seen most strikingly in the ventral portion of the pons, especially in the region of the substantia nigra, implicating the fibres of the third nerve as they pass out, and thus accounting for one of the most common symptoms of the disease.

In no case were any organisms, or bodies suggesting organisms, seen.

THE ADVANTAGES AFFORDED BY EXTENSION IN THE TREATMENT OF DISEASED JOINTS

BY SIR W ARBUTHNOT LANE, BART , M S , F R C S ,
CONSULTING SURGEON GUY'S HOSPITAL ETC

QUITE a number of years have elapsed since my views on the treatment of tuberculous, rheumatoidal, and other conditions of joints by means of rest were first shaken and then altered by the observation of the results of the combination of movements and extension afforded by Mr Hoefftcke's appliances Up to that time I was imbued with the view, then accepted, that rest was a factor of vital importance in the treatment of diseased joints I then learnt that if sufficient extension could be exerted to take pressure off the opposing articular surfaces of the affected joint movement was often most beneficial and often accompanied with little or no pain This is an illustration of the law to which I have frequently called attention—namely, that everything that is universally accepted as true in surgery is invariably false It is not possible to exert upon all diseased joints, such as those of the spine, enough strain to enable the application of this principle Yet even in these joints it points the direction in which we should work

Effect of the Apparatus on the Diseased Joint

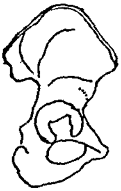
The advantages afforded by the forcible separation of the diseased articular surfaces from one another, combined with free movement, are best shown by the use of a really efficient extension apparatus for the leg, which does not interfere with the functioning of the diseased joint This is effected by the apparatus which Mr Hoefftcke has devised Not only does it exert great strain upon the articulation, keeping the surfaces from impacting on one another, but it permits of free movement of the joints of the leg, while enabling the sufferer to lead an active life It keeps the parts well supplied with blood, which flows more freely through the vessels of the affected joint, while the muscles are kept functioning normally

The method of cure is based on the same principle as that applied with so much success in the treatment of tuberculous disease of the lungs at the institutions at Frimley and elsewhere Since I first grasped the great advantage afforded by this principle, best applied by the apparatus already referred to, I have employed it largely with much success If a diseased joint is moved forcibly without being extended the articular surfaces are bruised or otherwise damaged, and acute inflammation follows only too frequently, whereas under the influence of extension the surfaces of the fixed or displaced joint can be moved freely on one another, so that such movement is followed by a minimum degree of rapidly subsiding inflammation The apparatus, by means of which a considerable amount of extension is kept up upon the affected joint, is applied to the limb and the patient at once proceeds to lead an active life

The mode of treatment varies to some extent with the joint affected In many hip conditions it is necessary to employ forcible movement and extension before the apparatus is put on, whereas in disease of the knee the apparatus is applied at once to the deformed limb, extension being exerted gradually subsequently Any residual flexion of the knee that cannot be overcome by the use of the splint alone can be met by forcible straightening of the limb on the extension table

The knowledge of the usefulness of the combination of extension and movement has served me in good stead in recent years, and I have been able to restore the functions of many joints which would otherwise have been fixed, probably in a bad position, and materially interfering with the usefulness of the individual

In 1887 I read a paper before the Royal Medico Chirurgical Society entitled "An Undescribed Method by which the Superjacent Weight of the Body is Transmitted in a United or Ununited Fracture of the Neck of the Femur through an Acquired Ilio femoral Articulation, and the Bearing of the Principle on the Surgery of the Hip joint ' In that I demonstrated, in cases of shortening of the upper extremity of the femur resulting from fracture of the neck of the bone or from disease of the joint, the mechanical advantages afforded by the formation of a new articulation in front of the transverse axis of pelvic rotation, since in these circumstances compensation for the shortening did away with the lordosis and the superjacent weight of the trunk was transmitted through a secure joint which allowed of a considerable range of movement I applied this principle with great advantage to cases of tubercular and other diseases of the hip joint fixed in a position of much adduction and flexion in which the active disease had become quiescent or in which the femur had ankylosed to the innominate bone In the latter case the ankylosed bone was divided and its extremity rounded by means of a coarse file If the femur was not ankylosed the stump of the residual head and neck was treated in a similar manner The surface of bone immediately below the anterior inferior spinous process of the ilium was then freely exposed, when a cavity of a shape and size suitable to accommodate the rounded end of the femur was cut in its outer aspect by means of a gouge (See figure) A thick piece of silver wire was then passed through a drill hole, which traversed the neck and upper end of the shaft of the femur from without inwards The floor of the cavity in the ilium was then perforated by the drill and the end of the wire was passed through it The extremities of the wire were drawn together and fixed in such a manner as to retain the newly shaped surfaces of bone near to one another, care being taken not to approximate the surfaces too closely so that they would move freely on one another without friction Movement around the axis afforded by the silver wire was commenced as soon as the soft parts had united After the lapse of several weeks the wire was removed, when rotatory movements were instituted and the normal range of function was restored as far as the conditions would permit I found that the younger the subject at the time of operation the sooner was a new joint developed and the more perfect was the result I was surprised to find how rarely tuberculous infection sprang up in old diseased joints dealt with in this manner



This figure represents the outer surface of the innominate bone The dotted circle shows the position of the cavity cut to accommodate the end of the neck of the femur

My subsequent experience of the extension splint has convinced me that this freedom from recurrence was due chiefly to the fact that the articular surfaces were prevented to a great extent from exerting mutual pressure by the presence of the thick silver wire on which they were threaded for a considerable time, while the nutrition of the patient s joint benefited by the free movements that were employed to develop the new articulation I have recently seen some of the cases on which this operation was performed in 1896 and 1897 and found that the new joints were still functioning efficiently Several of these cases were described and illustrated in the *Clinical Journal* of Oct 20th, 1897

The chief obstacle that I experienced in these operations, and especially in other than young children, was the great pain on movement I attempted to overcome this by various forms of extension apparatus, but could not obtain one which was in any way thoroughly efficient If at that time I had been able to avail myself of the use of a thoroughly satisfactory extension apparatus—which did not exist at that time—I should have been able to enlarge the scope of my usefulness very materially and in many cases have simplified the surgical procedures

A NOTE ON THE CLINICAL DIAGNOSIS OF DIPHTHERIA AND OTHER EXUDATIONS IN THE THROAT.[1]

BY HARRY DRINKWATER, M.D. EDIN.,
PHYSICIAN TO THE WREXHAM FEVER HOSPITAL.

BY clinical diagnosis I mean immediate diagnosis, at the bedside of the patient, by ocular inspection of the fauces, before a bacteriological examination is made.

A very considerable percentage of cases certified as diphtheria and sent as such into the fever hospital of which I have been in charge for between three and four years have been cases of follicular tonsillitis, influenza, or simple catarrh. On the other hand, many cases have been admitted in a hopeless condition of toxæmia, or only just in time for life to be saved by tracheotomy, the disease having been treated for several days as "quinsy." This uncertainty as to the differentiation of diphtheria from the simpler infections of the fauces is widespread, and medical practitioners are often in doubt apart from a bacteriological examination, which may mean a delay of 24 or 48 hours, with possibly disastrous results.

The thesis which I advance is that if certain visible characteristics are carefully observed, and more especially the distribution of the disease patches in the fauces, this uncertainty should seldom occur. As a matter of fact, my naked-eye diagnosis has been confirmed in every case by subsequent bacteriological examination, with the single exception of Vincent's angina, which cannot always be distinguished from diphtheria by the eye alone. In from 10 to 20 per cent. of cases of true diphtheria an examination of a swab-film is negative, and the Klebs-Löffler bacillus is only detected after cultivation in an incubator. Very often the swab has to be sent away by post, and there is inevitable delay. It is, therefore, obvious that if a diagnosis can be made by ocular inspection alone such means of diagnosis must have an immense advantage over the bacteriological method, however desirable the latter plan may be for purposes of confirmation.

If my plan of diagnosis has been uniformly correct for a period of over three years, in a hospital serving a district with a population of about 80,000, one is driven to the conclusion that exceptions must be few and far between. The points to be relied upon in making the diagnosis are illustrated by the drawings here shown; they are all hospital cases admitted as diphtheria.

The first point to note is the distribution of the patches, and for this purpose the fauces may be considered as divisible into six areas, three on each side of the mid-line, as shown in Fig. 1, where A B is the mid-line and the figures 1, 2, 3 are placed in the tonsillar, the uvular, and the palatal areas respectively. Every area may show some deposit, and in *any one* area the deposit may consist of a single patch or of several patches. The tonsillar area is the one most frequently affected. Now the important thing to observe is whether the tonsillar area (or any other area) shows *one* patch or more than one. If two or more patches are present on one tonsil or in one tonsillar area the disease is neither diphtheria nor Vincent's angina; most frequently it is follicular tonsillitis or influenza. In diphtheria the patch in *any one* area is single, and the same is true of Vincent's angina; in follicular tonsillitis and in influenza there are multiple patches in the tonsillar area.

In diphtheria the patch shows certain well-marked characteristics—viz.: (1) It is raised above the level of the mucous membrane. (2) The edges of the deposit are sharply defined all round. (3) The colour varies greatly; it may be white and glistening, bluish, yellow, or spotted with black or red. It rarely has the "wet wash-leather" appearance described in the text-books.

In a given case of membranous deposit on the fauces, if it is raised above the level of the mucous membrane, has sharply defined edges, and is single in each affected area, there can be no doubt that the disease is either diphtheria or Vincent's angina, and this diagnosis is arrived at in a few seconds without delay in waiting for a bacteriological report.

It is necessary to remark that these features are characteristic of the disease in the period of growth; after resolution has begun and the membrane is being cast off a number of isolated islands may be seen in the tonsillar area; but, of course, the diagnosis should have been made before this stage is reached. In diphtheria or Vincent's angina there may be five or six patches, but in neither disease do we see (in the period of growth) more than one patch in any one of the six faucial areas; each area may have one patch, but not more than one. If, then, in a given case two or more patches are seen in the tonsillar area the disease is not diphtheria, and a bacteriological examination is not required except for confirmation of the naked-eye diagnosis. The term diphtheria is applied to those cases in which Klebs-Löffler or Hoffmann's bacilli are present. If these germs are not present the disease is regarded as other than diphtheria.

Descriptions of Illustrations.

FIG. 1.—The areas of the fauces: (1) tonsillar area, between anterior and posterior pillars of the fauces; (2) uvular area; (3) palatal area.

FIG. 2.—Diphtheria. Single sharply defined patch in each tonsillar area; tonsils swollen.

FIG. 3.—Diphtheria. One patch in each tonsillar area; shows elevation of patch above surface of mucous membrane.

FIG. 4.—Diphtheria. Single patch on each side.

FIG. 5.—Diphtheria. *Thick membrane extending into all six areas;* edges sharply defined.

FIG. 6.—Diphtheria. *Involving every area except right palatal.*

FIG. 7.—Hoffmann's diphtheria. Distinguishable from Klebs-Löffler diphtheria only by bacteriological examination.

FIG. 8.—Vincent's angina The distribution is like that of diphtheria. The deep depression ("penetrating ulcer") in the patch *on the left tonsil is characteristic of Vincent's angina.*

FIG. 9.—Vincent's angina The thinning of the lower part of each patch is characteristic of Vincent's angina. It is not seen in diphtheria.

FIG. 10.—Double infection of diphtheria and Vincent's angina.

FIG. 11.—Double infection of diphtheria and Vincent's angina.

FIG. 12.—Influenza. Distinguished from *diphtheria and Vincent's* angina by having more than one patch in the tonsillar area.

FIG. 13.—Influenza. Showing *two patches on right tonsil.*

FIG. 14.—Influenza. The two patches on the left tonsil at once *distinguish it from diphtheria.*

FIG. 15.—Follicular tonsillitis. Tonsils congested. Pus oozing out of several follicles. FIG. 16.—Scarlet fever. FIG. 17.—Rubella.

FIG. 18.—Secondary syphilis. Thin deposit. The case was one of diphtheria which showed this appearance three weeks after admission to hospital.

The appearance of Vincent's angina as seen in the throat is very similar to that of diphtheria, so similar, in fact, that in many cases it is quite impossible to differentiate the two diseases. Vincent's angina may be said to mimic diphtheria, just as syphilis and hysteria mimic other diseases. Occasionally, however, we come across a case of Vincent's angina which can be at once recognised as such, owing to certain special features, the most characteristic of which is a sharply defined penetrating ulcer about the middle of the patch with its long axis running vertically, the deposit sometimes scarcely extending beyond the margins of the ulcer. Another peculiar feature is the marked thinning of the lower portion of the patch, making the inferior limit ill-defined. If either of these features be present Vincent's angina may be safely diagnosed. There is sometimes considerable erosion of the uvula. Sometimes the deposit is softer and more creamy than in diphtheria, whilst in other instances it is extremely dense and tenacious.

In follicular tonsillitis there is marked swelling and congestion of the tonsils, and muco-pus can be seen oozing out of several follicles. The single patch characteristic of diphtheria and Vincent's angina is never seen. In influenza the patches are multiple in the tonsillar area, and very often without any appreciable swelling of the tonsils.

Should these points be generally confirmed the conclusion would follow that, from the point of view of practical medicine, the naked-eye diagnosis at the bedside of the patient is incalculably more important than the bacteriological diagnosis, and that if generally acted upon there will result a considerable saving of life.

---

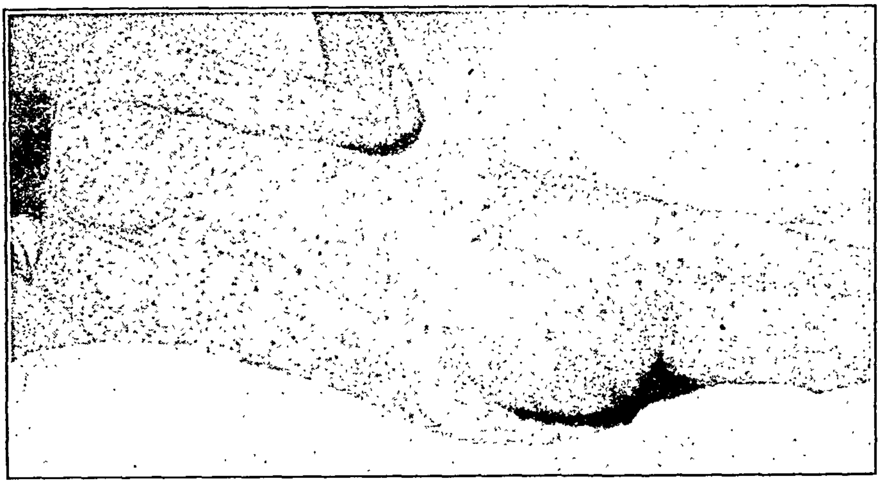
THREE CASES OF MODIFIED SMALL-POX.

BY WALTER ALLINGHAM, M.R.C.S., L.R.C.P. LOND.,

MEDICAL OFFICER OF HEALTH, ORSETT, ESSEX, RURAL DISTRICT COUNCIL.

THREE small-pox cases of unusual interest have recently occurred in this district. The following details may prove useful in the diagnosis of similar cases. All three followed the same course with varying severity in conformity with their vaccinal states, each exhibiting similar characteristics as regards rashes and distribution. In each case headache was followed in three days by a papular rash (on forehead and chest), rapidly becoming vesicular and gradually involving the whole trunk and extremities equally. Flexor surfaces were affected as much as extensor, with several spots in both axillæ; palms of hands, soles of feet, and soft palate quite free. The vesicles were discrete, soft, and flat; some were ovoid, not umbilicated, and collapsed on puncture. As no history of contact with small-pox could be obtained in the first case, the diagnosis of chicken-pox was made, but on the eighth day of the first rash a second rash made its appearance, unaccompanied by any constitutional disturbance except a slight headache in the mildest of the three cases. This secondary rash, which was petechial, deep, and somewhat shotty, affected those parts more especially involved in true small-pox—that is, the brow, wrists, extensor surfaces of forearms and legs, palms of hands, and soles of feet; in two cases vesicles were seen on the soft palate. By this time most of the first rash was becoming dry, but many vesicles still remained full of lymph and quite soft. The two rashes were quite distinct and could easily be differentiated.



An unusual case of modified small-pox (Case 2), showing profuseness of first rash on the back and secondary rash on forearm. The latter became thicker on the wrist and hand, which are not shown.

Details of Cases.

CASE 1.—Male, 69. Vaccinated in infancy. Headache and general malaise for three days, with some temperature; when first seen vesicular rash on forehead, chest, back, and extremities generally; successive crops appeared on following days, affecting both axillæ, but avoiding palms and soles; on the third and fourth days of rash temperature rose to 102° F. and patient was delirious. Next day temperature fell and patient felt practically well. During the following days fresh spots appeared, having all the characteristics of chicken-pox, until the eighth day, when a few petechial spots were first noticed on palms of hands. Next day soles of feet were similarly affected, and two small vesicles were seen on soft palate; papules appeared on face, trunk, and arms, some quite shotty. I then decided the case was small-pox, and ordered removal to M.A.B. hospital ten days after first rash appeared, since when I have lost sight of the case, but am informed that the patient made a good recovery.

CASE 2.—Male, 60, brother of the first case. Vaccinated in infancy; revaccinated on the day first case was removed to hospital. Onset, headache not severe four days after vaccination. Two days later a few papules appeared on forehead and chest; the next day forehead, whole trunk, arms, thighs, legs covered with vesicular rash, also axillæ, hands and feet free. Seven days after vaccination, which was successful, patient was moved to the local small-pox hospital. Fresh vesicles continued to appear daily until the whole body, except palms and soles, was involved, the spots being ½ to 1 inch apart. There was some swelling of the nose, where the spots were semi-confluent. Eight days after appearance of first rash two or three deep purple spots were noticed on terminal phalanx of each thumb, followed later in the day by a few on soles of feet. These were distinctly shotty and quite different in appearance from those seen in the first rash. Next day the new rash was well established, intermixed with the old, but affecting more especially the extremities and extensor surfaces.

The accompanying photograph, which I took 11 days after appearance of the first rash, shows how particularly the secondary rash had involved the forearm, and well illustrates the profuseness of the first rash on the back, which was only slightly affected by the second rash. No constitutional symptoms ushered in the second rash, and throughout the temperature never rose to 100° F. Subsequently some of the spots coalesced, to form large flat sloughs the size of a shilling; otherwise the patient was making a good recovery.

CASE 3.—Female, 61, wife of first patient. Vaccinated in infancy; revaccinated on the day her husband was removed to M.A.B. hospital. Onset, severe headache eight days after successful revaccination. Two days later a few papules on forehead and chest; numerous small vesicles on arm adjacent to vaccination groups. On the next day more vesicles appeared on chest, abdomen, axillæ, back and thighs, and arms—flat, soft and superficial, not umbilicated. The patient was then removed to local small-pox hospital. Small crops of vesicles continued to appear on successive days, but they were very scanty, showing no preference for the extremities. Two large groups of small vesicles like herpes occurred on chest and back; very few spots on the face, hands, and feet; beyond initial headache patient felt well and had no temperature. Nine days after first rash appeared a few petechial spots showed on soles of feet; patient had a return of slight headache for a few hours. Following this more spots of a deep nature became evident, intermixed with the other rash, but in this case neither rash became profuse. Subsequently seeds (dried-up contents of pocks) have been extracted from some of the pocks in all three cases, proving the secondary rash to be small-pox.

Remarks.

Reviewing these cases, which occurred without any history of exposure to small-pox, the diagnosis of chicken-pox on the first rash was, in my opinion, reasonable, and it was only after the first patient developed a secondary rash that I decided to isolate the subsequent cases at an early date. It might be wise to insist on isolation of chicken-pox for the first ten days.

AT the Royal Institution of Great Britain, the Friday evening discourse on June 4th will be delivered, at 9 o'clock, by Sir Ronald Ross, the subject being Science and Poetry.

THE NEED OF DENTISTS.—With regard to Professor Adami's call for 10,000 dentists, mentioned in THE LANCET of May 22nd (p. 1142), it is important to remember that there are only about 5000 registered dentists in the United Kingdom—a number little greater that in 1878, when the Dental Register was instituted—a number, moreover, quite insufficient to attend to the dental needs of the 5,750,000 school children alone, even if all dentists gave their whole time to school work. The number of dental students in Manchester University is now 130; nearly three-quarters of them are ex-Service men; there are 12 women students.

FULL-TIME TUBAL PREGNANCY

CÆSAREAN SALPINGECTOMY RECOVERY.

BY R ECCLES SMITH, O B E , M B , CH.B LEEDS,
F R C S EDIN ,
SURGEON TO THE SURGICAL HOSPITAL BARRY, GLAM

THE question of a viable child going to term in a Fallopian tube without rupture of the tube has been the subject of much discussion and diversity of opinion. Sir John Bland Sutton, after vast experience, refuses to acknowledge the possibility of such an occurrence So far, in the literature, I can find no case similar to the one I am recording, in which I believe complete rupture of the tube did not take place. I admit that incomplete rupture of one or more of the coats may have occurred in the earlier months, followed by sufficient reinforcement by adhesions and localised protective peritonitis (as shown by the repeated alarms) thwarting complete rupture, and allowing a viable child to go to full term until delivered by surgical interference

Dr. R P. Harris[1] collected 40 cases of removal of a living fœtus over seven months, with a mortality of 10 mothers and 13 infants Van Boll[2] records 46 maternal deaths out of 83 cases of operative treatment for pregnancy over seven months Sitner's[3] latest statistics show a 30 per cent mortality of the mother where the placenta was removed and the sac left, and 5 7 per cent where the whole or the greater part of the sac was removed. The fœtus in these cases did not apparently reach the full period.

The Case Described

Mrs P , aged 32 years, 3 para, nine years, eight years, and six years ago Children were born naturally and without difficulty Menses regular, and last seen April 10th, 1919, for five days On June 12th, presumably about the eighth week of pregnancy, she was suddenly seized with acute pain on the left side of the lower abdomen, with "cramp" in the left leg She was in bed for two days, and had what she thought was a copious menstruation for four days, resulting from an attempt at tubal rupture or abortion Some slight swelling of the left leg was noticed at this time Examination by her doctor showed an indefinite fullness in the left side of the pelvis, apparently not sufficient to diagnose a pelvic hæmatocele (small if present at all), but certainly suggestive of a pregnant tube Exactly seven days later another attack was recorded, similar to the above but of much less severity, with no external hæmorrhage and not necessitating rest in bed Every 14 to 21 days from this date up to term she had attacks of pain without hæmorrhage and insufficient to take her from her duties except for a few hours The patient went on with what she thought was a pregnancy ordinary in time but extraordinary in character In October and November she had frequency and incontinence of urine Associated with this was an offensive vaginal discharge A coli cystitis (cultured later) was present

On Dec 22nd I saw her in consultation with Dr W P Starforth of Barry She had been in labour for some 16 to 20 hours The pains were frequent and strong To observation and palpation the abdomen suggested a full time pregnancy, the fundus of the "uterus" being pushed over to the right side Vaginally the cervix was extremely high up almost out of reach There was an old tear and a marked erosion with endocervicitis producing an offensive discharge The cervix was only slightly softened and partly dilated but not in keeping with a cervix of labour Per rectum there was a large hard mass at the pelvic brim on the left side, corresponding to the head of the infant The uterus was not defined, but thought to be the enlarged sac felt in the abdomen

The diagnosis of obstructed labour was made, conjecture being that this was due either to a rigid cervix or to some parametric tumour I may say here that the earlier history was not fully gathered at the time of the examination, as the original medical attendant had left the case without recording the early symptoms, and the patient s disjointed story of an early threatened abortion was taken too much for granted Operative measures were advised

Operation —Median incision 8 inches long An apparently full time pregnant "uterus" was carefully packed off from the abdominal cavity During this process a strong band across the upper pole of the gestation sac thought to be an adhesion of the great omentum, was felt Incision into the "uterus" proved this sac to be abnormally thin walled The infant was rapidly evacuated, the head being in the pelvis The lack of the usual contraction of the "uterus," in spite of a prior injection of 1 c cm of pituitrin, gave rise to a suspicion of extra uterine gestation A normal placenta was stripped off from the upper and posterior walls of the gestation sac Careful exploration of the sac did not reveal any rupture Except at the placental site the walls were homogeneously smooth, and the infant was completely covered by the gestation sac There were no signs of a pelvic hæmatocele or of organised clot of any dimensions, so that if rupture had taken place it must have been incomplete or negligible The true pelvis was then explored A slightly enlarged normal uterus, right tube, and ovary were present The left tube for half an inch was normal, and then expanded into the gestation sac The sac, now rapidly filling with blood, was momentarily packed and reinspected The band mentioned turned out to be the pelvic colon stretched over the sac, the layers of the broad ligament having been pushed up before the increasing tube The peritoneum was quickly incised and stripped off the sac It was not possible to free the pelvic portion of the sac completely The left tube was then ligated at its attachment to the uterus and the right tube ligated and divided for sterilisation The main part of the sac with the portion containing the placental site was clamped off and removed A few deep mattress sutures to approximate as far as possible the walls of the remainder and a running suture to bring together the edges of the sac and arrest hæmorrhage were inserted Hæmostasis completed, the peritoneum was then closed Rapid abdominal toilet and closure of the abdomen without a drain completed the operation in under an hour

The child was fully formed, well nourished, of good colour, and weighed 5¾ lb The head was markedly flattened over the left parieto-occipital region The right side of the neck was completely depressed as though a ball had been pressed into it The mandible on the right side was almost semilunar with the concavity upwards These temporary deformities are rapidly being rectified by nature.

Except for the passage of a clot per vaginam (no decidua) and a slight chest complication the mother made an uninterrupted recovery, and went home in a fortnight About 14 days later she had some further bladder disturbance, which rapidly cleared up with urinary antiseptics Examination reveals nothing abnormal in the left side of the pelvis except a little thickening

Report on the sac by Dr KNYVETT GORDON (The portion was taken from the edge of the sac)

"This specimen is a portion of the Fallopian tube much stretched and thinned, and with the epithelium almost obliterated by pressure Between the muscle fibres are masses of fibrin and leucocytes No decidual cells or chorionic villi are present "

I am indebted to Dr Starforth for his assistance at this case, to Dr Lawrence Pick for a very difficult anæsthetic, and to Dr Gordon for his careful report on the section

For the kindly interest, advice, and examination of the specimen I am deeply grateful to Sir John Bland Sutton, on whose dictum that full time tubal pregnancy without rupture is not possible this case appears to me to throw some doubt

LIMITATION OF PANEL PATIENTS IN ABERDEEN.—On May 17th, at a special meeting of the Aberdeen Burgh Insurance Committee, it was agreed, among other things, that the total number of patients on a doctor's panel must not exceed 2500

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN —The annual general meeting of this society was held on May 19th Sir Alfred Pearce Gould in the chair Sir Malcolm Morris and Dr J Needham were elected Vice Presidents and eight new directors were also elected to fill the vacancies in the Court The society consists at the present time of one honorary, 160 life, and 135 ordinary members making a total of 296, and from an investigation of the figures for the past 25 years it appears that the total number of members remains practically stationary, the expenses have not increased, and they have been met by the subscriptions The invested capital has increased from £95 700 in 1895 to £144,250 in 1920 this increase having been due mainly to the large legacy received from the late Mr Brickwell The annual grants during the same period have increased from £3280 10s 5d to £4937 19s 10d. Further particulars of the society may be obtained on application to the Secretary at the offices of the Society, 11, Chandos street, Cavendish square, W 1

BRONCHO-PULMONARY SPIROCHÆTOSIS (CASTELLANI) SIMULATING PULMONARY TUBERCULOSIS.

BY C. LESLIE BROWNE, L.R.C.P., L.R.C.S.,
ASSISTANT MEDICAL SUPERINTENDENT, CLARE HALL SANATORIUM.

CONSIDERING the importance of the question of pulmonary tuberculosis at the present time, the following notes of two cases occurring in Clare Hall Sanatorium may be of interest.

CASE 1.—E. B., aged 47 years, male, admitted on May 5th, 1919. Born in London and lived there all his life. Health has always been good till nine years previous to admission, when he had a severe attack of bronchitis. This left him with a cough, which continued slight till October, 1918, when a second attack of bronchitis ensued. After recovery cough still continued and became very persistent. About the middle of February he had an attack of hæmoptysis, quantity about an ounce. Between the middle of February and the end of April he had five similar attacks, and on each occasion the amount of blood was about an ounce. No family history of T.B. traceable.

The general condition of patient on admission was fairly good and temperature was normal.

Lungs: Signs of bronchitis present.

Mouth: Some carious teeth present, with spongy gums, bleeding easily on pressure.

Pharynx: Injected, but no definite soreness present. Patient did not feel his throat sore.

Sputum: Frequent and careful examinations were made. No T.B. were found, but spirochætes were present in enormous numbers. Sputum was almost purulent in character, with an offensive odour.

As secretion taken from crypts between teeth and gums showed heavy infection with spirochætes great care was taken in having the mouth thoroughly washed with antiseptic lotion just before obtaining sputum. This made no difference in the enormous numbers of spirochætes.

Morphology of spirochætes.—Actively motile; length from 7 to 29 μ, with tapering ends; spirals varied from 2 to 9, and quite irregular. An occasional one with regular spirals was found. On staining, carbol gentian violet gave the best and clearest definition. Fontana's method also gave a good picture. The Romanowski stains were not quite so successful. The spirochætes were Gram-negative; Benian's stain presents an excellent picture.

Treatment.—Arrhenal (disodium methylarsenate) was given by mouth in ½-gr. doses, twice daily for some weeks. There was a slight diminution in the numbers of spirochætes at the end of this period and an improvement in the general condition of the patient. Cough was less persistent. Kharsivan in doses of 0·1 g. was next given intramuscularly till 1·2 g. had been administered. Under this treatment the number of spirochætes diminished rapidly, cough became considerably less. Patient slept much better and his general condition was very satisfactory. On discharge spirochætes were still present, but not many. A mouthwash was used throughout the course of treatment and the teeth were attended to by a dentist. This patient had no recurrence of hæmoptysis while under treatment here.

CASE 2.—D. L., aged 28 years, female, admitted on July 21st, 1919. Trouble commenced with hæmoptysis in March, 1915. Since then it has been frequent, sometimes daily for seven or eight days consecutively, and she has been in the following institutions: Chelsea Hospital, March to November, 1915; Clare Hall Sanatorium, November, 1915, to January, 1917; Neasden Isolation Hospital (T.B. ward), January to June, 1917; Eversfield Chest Hospital, St. Leonards, August, 1917, to June, 1918; Middlesex Hospital, November, 1918, to March, 1919.

Patient was born in England, and has always lived here, except for three years—1911 to 1914—spent in Canada. She states that in November, 1912, she was operated on for gastric ulcer, and had a second operation for the same purpose a month later. In the winter of 1913 she had an operation for appendicitis. On her return to England she developed intestinal obstruction, and was operated on at St. Mary's Hospital, Paddington. Later in the winter of 1914–15 she had pneumonia and pleurisy, which left her with a cough. Her first attack of hæmoptysis followed shortly after.

On the first day of admission to the sanatorium she had a small hæmoptysis—about an ounce at most. During her stay here she has had frequent hæmoptyses, varying from 2 drachms to 4 ounces, and sometimes more. On five or six days in succession she has produced coloured sputum. Routine examination of sputum showed enormous numbers of spirochætes. Examination of mouth showed some decayed teeth with spongy gums, which bled easily on pressure. Examination of secretion from crypts between gums and teeth also showed enormous numbers of spirochætes. The same precaution was taken as in Case 1 to prevent sputum examined being contaminated from the mouth. Frequent and careful examination of sputum showed no T.B. Physical signs in the lungs were those of bronchitis, and were practically the same as when here in 1916. Abdomen showed operation scars. Stomach dilated; colon dilated. Constipation, with passage of large amount of mucus. There was much pain before and after motion. The character of hæmorrhagic sputum was a peculiar pink mixture, as described by Violle, with minute air-bubbles intimately mixed. The amount of blood was always considerably less than it appeared to be, there being quite a large proportion of watery sanguineous fluid with the thicker portions floating on the surface. The microscopic characters of the spirochæte were similar to those mentioned in Case 1.

Treatment.—At first this was directed to the alimentary tract and then arrhenal was given, but at the end of three weeks severe gastro-intestinal irritation was set up and it had to be discontinued. This soon improved and general treatment was given. Patient refused treatment by kharsivan. In spite of unsatisfactory treatment, the general condition improved and the spirochætes diminished considerably in numbers at the time of discharge. She was still producing colour expectoration when she left.

Remarks.

As far as I am aware, no case such as those described has been published as having occurred in England. Castellani first observed this condition in Ceylon in 1905, and his observations were confirmed by others in tropical parts. Later, in 1915, some cases were seen by Galli Valerio in Switzerland, Lurie in Serbia, and Castellani in the Balearic-Adriatic zone. In 1916 some cases were found in France by Violle, and in 1917–18 a few cases were observed by Rubière and Gautier in France among French and Indo-Chinese. Violle, in THE LANCET of Dec. 7th, 1918, remarks, "except in one single case, none of my patients had any mouth lesions of spirochætal origin," and Rubière and Gautier, writing in the *Journal of the Société de Biologie de Paris*, remark on the "absence of pharyngeal or dental lesions." In both the above cases the dental lesions were marked and, as noted, spirochætes were present in enormous numbers in the exudate. In other respects these two cases appear to agree with the description given by the writers mentioned. The physical signs in the lungs were those of bronchitis, the body was fairly well nourished, and the temperature normal. D. L. (Case 2) sometimes had a rise of temperature for a few days, but this was apparently due to other conditions. It will be noted that neither of these cases had any connexion with Eastern parts or peoples, and E. B. (Case 1) had never been out of England.

There is a proportion of cases in all sanatoriums with negative sputum, and a routine examination of such negatives might give a satisfactory explanation of some of them.

A CASE OF
HYDATIDIFORM MOLE IN A MULTIPARA AGED 51.

BY H. H. GELLERT, M.B., CH.B. EDIN.,
LATE SENIOR RESIDENT, METROPOLITAN HOSPITAL, E.

Bona fide cases of pregnancy occurring after the age of 50 years are possibly sufficiently scarce to merit their publication from the point of view of interest as well as of statistics.

The patient, a multipara, aged 51 years 11 months, was admitted to the Metropolitan Hospital on Feb. 9th, 1920, complaining of continuous hæmorrhage per vaginam, persistent vomiting of three weeks' duration, and increasing weakness. A mass occupying the pelvic cavity and palpable through the lower abdominal wall suggested a diagnosis of fibroid tumour of the uterus, and the patient was admitted with a view to having hysterectomy performed.

Previous history—Married 27 years, eight children, all normal confinements, youngest child 7 years old, no miscarriages Had never been robust, and was addicted to headaches anorexia, and slight dyspnœa Catamenia perfectly regular up to November, 1919, when she had her last normal period, after which she saw nothing till Jan 20th, 1920 From that date she started to lose and continued for a week This she imagined to be another period About this time she began to feel ill and started to vomit The hæmorrhage commenced again after a week's cessation and had continued ever since, increasing in amount, and at times slightly offensive She rapidly became weaker, the vomiting was persistent, occurring at all times of the day or night, and she was unable to keep food down at all She had lost weight Since Jan 20th she had noticed some tenderness over the lower part of her abdomen, especially on the right side, vertigo and a dull ache in the lower part of the back were also present No increase in the size of the abdomen or breasts had been noticed by the patient There was no history of constipation, retention, frequency, or pain on micturition, and no family history of syphilis

Present condition—On examination the following points were noted A tired, ill looking woman, anxious appearance, slightly jaundiced and anæmic Temperature 99 4° F, pulse 104 Tongue coated, breasts small and flabby, no secretion evident Abdomen showed no marked distension On palpation a smooth, globular lump slightly tender, rising just out of the brim of the pelvis, could be felt through the lower abdominal wall, and was slightly inclined to the right side of the middle line No uterine souffle heard Vaginal examination No discolouration of vulva, a mass was felt in both fornices, filling up the pelvic cavity, and continuous with the tumour palpable through the abdominal wall, firm, elastic, and definite in outline No softening of the cervix could be detected The urine was acid and deposited mucus No albumin or other abnormal constituents were present

During the three days the patient was under observation prior to operation the temperature remained at 99 4° F, and she continued to lose blood No vomiting actually took place, but there was nausea and retching on occasions No renal or pulmonary condition was found to account for the toxic appearance of the patient This debilitated condition gave rise to a momentary doubt as to the wisdom of submitting her to operation at once, but in view of the fact that the metrorrhagia was decidedly increasing in amount it was considered advisable to open the abdomen

Operation—After a preliminary catheterisation and plugging of vagina the abdomen was opened in the middle line and an enlarged uterus the size of a four months' pregnancy, was seen rising above the brim of the pelvic cavity, it was tense, elastic, regular in outline, and showed all the characteristics of early pregnancy After incision of the fundus the uterine cavity was explored with the finger The contents were found to be an hydatidiform mole, consisting of the typical chorionic villi in the form of gelatinous cysts The mole was loosened by "curetting" with the finger and the whole cavity systematically cleared No serious hæmorrhage was encountered The uterine incision was sutured and invaginated and the abdomen closed in layers Subsequently ergot was given hypodermically and the hæmorrhage per vaginam gradually ceased The patient's recovery has been uninterrupted

The failure to recognise the possibility of pregnancy, in spite of a somewhat suggestive occurrence of a short period of amenorrhœa, may in view of the age of the patient be considered a permissible lapse in the framing of a diagnosis

I am indebted to Mr Clifford White, under whose care the case was admitted, for permission to publish the details

---

HEALTH CERTIFICATES BEFORE MARRIAGE —Our Vienna correspondent writes that the Austrian Board of Health intends to follow the example of several other States —for example, the United States and Bohemia—and attempt to make marriage more safe by requiring from both intending parties a certificate of health from a competent medical man The necessity for such a certificate is illustrated by the fact that the health of the Austrian population is much worse than ever before Professor Oppenheim, the leading specialist on syphilis and dermatology, states that 72 per cent of all prostitutes are now diseased, as against only 9 per cent before the war This increase of disease endangers the individual, and causes widespread sterility of marriages or illness of the offspring, acting most harmfully on the population In the Act of Parliament by which this health certificate is to be made legal provision will be made also to favour large families by taxation allowances to couples with more than two children, the advantages increasing with the number of children

Medical Societies.

ROYAL SOCIETY OF MEDICINE

SECTION OF OTOLOGY.

EXHIBITION OF CASES AND SPECIMENS

A MEETING of this section of the Royal Society of Medicine was held on May 21st, under the presidency of Mr. HERBERT TILLEY

Rapid Recovery from Acute Mastoid Suppuration.

The PRESIDENT showed a woman, aged 42, who was found to have the right antrum full of pus Owing to subacute inflammation in the first molar, that tooth was removed, when pus issued from the socket Despite daily irrigation of the antrum the discharge continued, and the right middle ear became inflamed, and the drum membrane perforated. During the next ten days the pain settled in the mastoid and parietal region. He opened the right mastoid antrum and cells, which were infiltrated with pus The parts were well cleansed, smeared with B I P, and the skin wound sutured in its whole extent Immediate union took place, and improvement was continuous She had left the home in a fortnight Her hearing was so good that she could hear a colloquial whisper at 8 feet, and the ticking of a watch at 8 inches

Mr. E M WOODMAN congratulated the President on his result, and told of a very satisfactory experience he had had with the same treatment since Mr. Tilley brought it forward a year ago It seemed that the more dirty the cases the better they did But he would not advise this precise treatment in cases in which there was infection of the lateral sinus, with rigors and high temperature —Sir CHARLES BALLANCE said he did not think there could be a better or quicker result in a bad case of acute mastoid disease To get healing in a fortnight in such a case was a triumph of surgery.

Tumours of the Eighth Nerve.

Mr. J S FRASER (Edinburgh) presented a careful statement on the ætiology and pathology of these tumours, with a dissertation on their microscopical appearances, clinical aspect, diagnosis, and the responses of the patients to hearing tests This was supplemented by a series of beautiful photomicrographs and notes of four typical cases These tumours may originate in the dura mater, the pia arachnoid, the peri- or endo neurium, or the sheath of Schwann The tumour might only affect the vestibular nerve, or occur only in the modiolus of the cochlea The tumour consists of fibres and nuclei, the former running in all directions, and hæmorrhages are often noted. Sometimes bundles of well preserved nerve fibres are seen running through the tumour In his four cases there was marked involvement of the labyrinth, and in one of them the perilymph space was crowded with fibrin, this, apparently coinciding with the "choked disc" in eye conditions, he termed, after a foreign observer, "choked labyrinth" The usual age incidence was 30 to 50 years With regard to symptoms, the first were nearly always auditory and vestibular—tinnitus, giddiness, and deafness, next headache, increased on stooping, unsteady gait, with tendency to fall to the side of the lesion. There were also diminution or loss of corneal reflexes, diplopia, and slight facial weakness, and later, difficulty in swallowing, cerebellar seizures, convulsions and loss of consciousness, anosmia, loss of memory, &c Unless these tumours could be diagnosed much earlier than at present it was almost useless to operate Radiograms of the two ears had not been helpful Nerve deafness with loss of the lower tones, in the absence of middle-ear disease, was held by Rhese to indicate the probability of acoustic tumour.

The PRESIDENT and Sir CHARLES BALLANCE spoke highly of the value of Mr Fraser's researches as shown in his exposition of this series of cases.—Mr. W. M. MOLLISON referred to one case of acoustic tumour upon which he had operated. The patient had the symptoms which Mr. Fraser described, and she was completely deaf. The tumour he removed from the eighth nerve was the size of a hazel-nut, and she made an excellent recovery. She died, however, of mental symptoms three months later.—Mr. **SYDNEY SCOTT** also expressed his appreciation of Mr. Fraser's work. The "choked labyrinth" which the latter spoke of was not present in all cases. There were many intracranial tumours which were not necessarily auditory nerve tumours, and it was only when the auditory nerve became defunct that one could be certain a case was one of unilateral auditory nerve tumour. Patients suspected of having the latter condition should be kept under observation by their medical attendant; it would be wrong to tell them that nothing could be done for them. When the patient was very tolerant of the passage of the Eustachian catheter, he suspected fifth nerve anæsthesia. He agreed as to the significance of loss of lower-tone hearing in the diagnosis of acoustic tumour. He had seen about 30 of these cases.—Dr. **JOBSON HORNE** referred to a case in 1898, in a woman, aged 54, who, four years later, died insane. If these tumours were congenital, he asked why they took so long to develop sufficiently to cause symptoms.—Mr. E. D. **DAVIS** thought these cases must be rare; in 12 years' ear work he had seen only two possible cases of the condition. Unilateral nerve-deafness caused one to think of the likelihood of the case being one of acoustic tumour.

Atresia of Auditory Meatus.

Mr. H. BEDFORD **RUSSELL** showed a man, aged 24, the subject of atresia of the left external auditory meatus. There had never been any discharge from this ear, and the hearing was remarkably good, while there was very little loss of bone conduction. He proposed to remove the diaphragm and to skin graft.—The **PRESIDENT** referred to a bilateral case of the same kind which he had five years ago, in a stout woman whose condition dated from scarlet fever which she had as a child. She refused operation, and hearing was improved and the tinnitus relieved by catheter inflation.—Mr. T. B. **LAYTON**, Mr. **SCOTT**, Mr. **MOLLISON**, and Mr. **LAWSON WHALE** also discussed the case.

Destruction of Ear-drum by Hot Liquid.

Mr. L. **COLLEDGE** showed a patient who, four months ago, upset a cup of hot tea over her right ear. Two months later there was much discharge from and swelling of the meatus. Antiseptic treatment led to improvement, but left a perforation, including almost the whole of the membrana tensa. There was complaint of much tinnitus on that side, which bromide scarcely relieved.

SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

ÆTIOLOGY OF PELLAGRA.

AT a meeting of this society held at 11, Chandos-street, London, W., on May 14th, with Professor W. J. **SIMPSON**, the President, in the chair, Dr. E. J. **WOOD** read a paper on the Ætiology of Pellagra from the Standpoint of a Deficiency Disease. Considerable attention has been directed to this important subject in recent issues of THE LANCET by papers from Dr. A. D. Bigland and Dr. J. I. Enright, giving their experiences of the disease among Ottoman and German prisoners in Egypt, and challenging the view that a food deficiency is the sole cause; by a leading article summarising the conflicting opinions and theories as to its origin, and by a digest of the valuable report of the Committee of Inquiry on Pellagra in Egypt in 1918. It is probable that the findings contained in this report attain as near an approach to the correct solution of the much-vexed problem of the ætiology of pellagra as is at present possible.

With these results Dr. Wood found himself in close accord, and the support given by him is of considerable value, based as it is on a close original study of the disease existing in the State of North Carolina, U.S.A., and viewed from the aspect presented to an American mind. His observations are drawn from a part of the world widely remote from that in which recent British inquiries have been pursued, and presenting entirely different conditions of living and general hygiene. It is a striking fact that the first reference to the occurrence of pellagra in America is as recent as 1907. Dr. Wood's first cases were seen in 1905, and despite careful inquiry of older physicians he could obtain no evidence of its existence prior to that date. He further remarked the noteworthy fact that between the years 1905 and 1909 the disease assumed a malignant and fulminating type in North Carolina suggestive of its first invasion of a virgin soil, comparable with the devastating effect of the original introduction of measles among the Fijians. Since this period pellagra had assumed its more chronic form as found in the eastern hemisphere.

Valuable Results by other Workers.

Dr. Wood reviewed the recent valuable work done by W. H. Wilson in Cairo, of P. B. Boyd and his co-workers in Egypt, from the standpoint of a food-deficiency disease, and the conclusions drawn by them as to the dangerous influence of a fall in the biological value of the protein of the diet in the production of pellagra, as well as the important part played by diarrhœal disease in disturbing the protein balance. K. Thomas had shown that in maintaining nitrogenous equilibrium various substances differed widely; the biological value of vegetable protein, especially that derived from maize, was found to be less than that of milk or meat protein in a ratio of about one to three. This inferiority of the maize proteins was regarded as explicable by the large amount of zein, which is devoid of both tryptophane and lysine—two amino-acids essential for animal nutrition.

Dr. Wood fully endorsed the important conclusions of Joseph Goldberger as the result of observations based on (1) the dietetic origin of the disease; (2) its dependence on some undetermined error in diet, with a disproportionately high vegetable and a disproportionately low protein component derived from animal or leguminous sources; (3) the absence of pellagra among those consuming a mixed, well-balanced, and suitably varied diet. Attention was drawn to the atypical distribution of the skin lesions in Goldberger's cases and to the criticism of the correctness of diagnosis, which was refuted by the definite evidence that no part of the skin surface was exempt from invasion, even the scrotum, vulva, the back of the knees, and elbows, as shown by some of Dr. Wood's own pellagrous patients. Mention was made of the supposed influence of bacterial infection through the agency of imperfect sewage disposal, regarded as an ætiological factor by the Thompson-McFadden Commission, McCullum, and others. The infective origin of the disease had at one time met with Dr. Wood's support until it was disproved by the results of the heroic experiments of Goldberger and his volunteers, who exposed themselves to infection by consuming the fæces, urine, and desquamations of pellagrins, without anything suggestive of the disease appearing. In spite of this evidence against infection, the possibility of an infectious element playing perhaps a secondary, but not less essential, part could not be excluded.

Distribution of Pellagra in North Carolina.

Interesting facts as to the distribution of pellagra in North Carolina were introduced by means of a map of the State, and it was pointed out that the disease was chiefly confined to the foothills of the high mountains bounding the western frontier, and that, as a rule, its incidence was much less along the Atlantic seaboard, whilst in the mountains themselves its occurrence was very rare. Its distribution at one time suggested the influence of some insect pest, but this had not been demonstrated. A direct relationship between lines of travel and the topography of the disease might also have been viewed as evidence of the spread of infection. The food factor, however, eventually afforded a surer guide in tracing the probable source of the disease, one evidently independent of the vitality, mode of living, or hygienic conditions which might prevail among the inhabitants, either of the mountains, foothills, or seaboard.

The dwellers in the mountains were described as being the most degraded type of Anglo-Saxon known, lowered by inbreeding for the past three centuries, and often living in most insanitary and overcrowded huts, on a diet far from ideal. Yet the mountaineer did not suffer from the disease. His food consisted chiefly of maize ground in toto at the local water mill and consumed before rancid decomposition of the germ could occur. On the other hand, the inhabitants of the foothills—workers in the local cotton mills—availed themselves of whatever was provided by the local merchant in the form of commercial maize, meal, and patent wheat-flour, and adopted whatever means would curtail and facilitate the cooking process. In consequence their food was composed of wheat flour without cortex maize meal milled without bran or germ, and a variety of chemical rising agents It was among the consumers of this diet that pellagra prevailed Dr Wood described this circumstantial association very concisely in the following words "It was interesting to trace the outbreak of pellagra in a village, timing its appearance with the abandonment of the old grist mill to which each farmer carried his small portion of cereal for primitive grinding There seemed to be a striking coincidence of the disease with the adoption of modern errors in milling and cooking"

Effect of the Milling Process on Maize

It was in consequence of Goldberger's influence and work that Dr Wood undertook to view pellagra from the standpoint of beri beri as a deficiency disease He was at once attracted by the report of P A Nightingale, published in 1912, on the occurrence of what there could be no doubt was pellagra among prisoners in a gaol in Rhodesia, attributable to the replacing of the normal diet of hand ground maize (ropako) by commercial "mealie meal" It was realised that this change was the responsible cause of the outbreak and, as soon as a return to "ropako" was made, the beneficial result was "immediate and magical"

Impressed by this report of Nightingale's, Dr Wood set out to learn to what extent maize suffered in the milling process He found that in the modern steam milling the grain was degerminated—i e, deprived of the germ, which was later ground separately, and with the bran sold as cattle food, having a great reputation as a milk maker The reason given for the modern plan of milling was that if the grain was milled without separating and removing the fat containing germ, the resulting product readily became rancid, for the germ of maize, being quite soft and poorly protected was the first to suffer if deterioration occurred Dr Wood made allusion to the belief of Lombroso that pellagra was due to a toxicity arising from the destructive action of various moulds on the essential portion of the grain, and expressed the opinion that if Lombroso had substituted the word deficiency for toxicity he would have been in close accord with many modern views

Pellagra Considered from the Same Standpoint as Beri beri

Dr Wood, in regarding pellagra from the ætiological standpoint of beri beri, recalled the work done in the Philippines, which showed that phosphoric acid (P_2O_5) was a reliable indicator of antineuritic substance in the experiments with polished rice and beri beri With this in mind he found that the commercial maize germ product contained 1 15 per cent of P_2O_5, and specially milled germ often as much as 2 per cent Per contra maize milled in Ohio contained only 0 29, and when ground in toto with no removal of germ, the grain yielded 0 78 per cent P_2O_5, further, bearing out the occurrence of the antineuritic substance in the cortical portion of the grain, their analyses showed that bran portions of wheat contained 0 98 per cent of P_2O_5, while average wheat yielded only 0 14 per cent

It was noted that the bran and germ portion richest in P_2O_5 and antineuritic substance are those rejected in the modern milling process and converted into cattle food Experiments similar to those undertaken with polished rice, but with the substitution of degerminated corn, were made on pigeons and resulted in the production of droopiness, loss of feathers, and a red legged condition, somewhat analogous to the polyneuritis gallinarum caused by polished rice This condition was relieved by administration of good maize, also by the alcoholic extract of the germ of maize, and in almost as striking a manner, by means of fresh cows' milk

From his experiments Dr Wood was led to suspect that the deficiency was one of water soluble B rather than of fat soluble A Applying this to the treatment of pellagrins, he considered that the deficiency could be more readily remedied by giving milk, fresh vegetables, and meat, by the consumption of the whole cereal without removal of the germ, also by avoiding the use of bicarbonate of soda as a rising agent, it having been found that the balance between acid and alkali in many baking powders was one very crudely struck

The question was not so much of the particular cereal at fault, as of the portion removed in the process of milling, and applied equally to wheat as to maize and although nutritional errors—a too low protein level or a too low biologic protein—without doubt played a large part in the ætiology of pellagra yet Dr Wood could not exclude the possible influence of an infectious element in playing a secondary but not less important role In the light of the observations of Enright Jobling the Thompson McFadden Pellagra Commission, McCullum and Sambon, he considered that the problem of pellagra could not yet be regarded as solved

Discussion

The PRESIDENT welcomed Dr Wood's valuable contribution to the study of pellagra He drew attention to the possibility of a dual ætiology from an infective source as well as a nutritional deficiency, and compared the instances of tuberculosis and leprosy, in which dietetic deficiency or error may be associated with a microbic cause

Dr P H. MANSON BAHR gave support to the views of Enright and Bigland He claimed that too great stress had been laid on the food deficiency theory as the main cause of the disease, and held that the theory of infectious origin was effectually disproved Food deficiency, he maintained, did not explain the occurrence of the 65 cases of pellagra among 70,000 German prisoners in Palestine and Egypt who had suffered no previous food shortage, many of them in good physical condition, not afflicted with dysentery or malaria He asked why, if pellagra was due to a food deficiency, there had been no cases in Austria, where tuberculosis and rickets were so rife as the result of food shortage. He suggested as a possible explanation of the occurrence of pellagra in Egypt, especially among well fed German prisoners, the action of a toxin peculiar to the endemic areas in Egypt affecting the endocrine glands, and particularly the suprarenals, which, together with the sympathetic system, bore the brunt of the disease In making this suggestion he drew attention to the similarity of pellagra and Addison's disease, as well as to the resemblance between the intestinal lesions of sprue and pellagra

Colonel S P JAMES sought explanation of the seasonal variation of pellagra if the latter were due to diet deficiency, on the ground that the diet remained the same, irrespective of the season, in pellagrins He pointed to the possible influence of sunshine, in that there existed a close agreement between the maximum of sunshine and the greatest incidence of pellagra. The highest peak of the charted hours of sunshine was found invariably to be a month in advance of the highest peak of pellagra cases, and similarly the secondary peaks of the two were found to agree to a corresponding extent If a second element existed in the causation of pellagra he seriously questioned its being an infective agent.

Dr H S STANNUS, with reference to seasonal influence, regarded the association of maximum sunshine and pellagra only to hold good in so far as the skin lesions were concerned, and that the influence of sunshine had no bearing on other aspects of the disease He referred to his experiences in Central Africa and mentioned that, though some food deficiency was a factor in the production of the disease, among gaol prisoners there were certain who suffered from pellagra without having eaten maize, yet others who ate maize remained free from the disease

Lieutenant Colonel P S LELEAN, R A M C, supported food deficiency as the main cause He referred to the conditions prevailing among Turkish prisoners from Gallipoli and Syria, and the absence of any source of infection in the towns of Syria, where the disease was unknown to Syrian civilian doctors Among a batch of 400 prisoners who had experienced considerable food shortage there had been 279 cases of pellagra, which subsequently, under the influence of improved conditions in the prison camp, had dropped to 27 Similarly, in the Armenian refugees' camp, as the result of short rations, pellagra occurred, but later disappeared on the improvement of the food supply. The striking contrast presented by the adjacent prison camps at Maadi, the one with 6000 Turks and many cases of pellagra, the other with 2000 German prisoners in good physical condition and presenting no cases of pellagra, could only be accounted for by a difference of diet The occurrence at a subsequent date of 65 cases out of a total of 70,000 German prisoners, he maintained, could be explained on the score of a food deficiency, by the effect of heavy work when on a light diet calculated as sufficient to meet the ordinary demands of life, also by the failure of extra supplies, which had at first been met through charitable agencies on behalf of prisoners, but had subsequently not been forthcoming in the later period of the war. The deviation of the biological protein of the light diet in response to the increased demands of heavy work, even if digestion and assimilation were correctly balanced, would, he considered, create a deficiency sufficient to account for the occurrence of pellagra.

Dr. W. H. Willcox and Dr. T. P. Beddoes also took part in the discussion, the latter drawing attention to the variation of the skin lesions as the result of exposure to heat, the most exposed areas—e.g., the back of the hands, the front of the knees, and instep—suffering most often. He also referred to the seasonal variation of the disease in its possible influence on the production of skin and digestive lesions, and, in advanced cases, of mental disturbances.

Dr. Wood, in his reply, stated that he viewed the whole problem of the ætiology of pellagra with an entirely open mind, and could offer no clear solution. Although in the main he had relied on Goldberger's work, which accorded with the report of the Committee in Egypt, as affording the most probable explanation of the disease, he admitted there were still unexplained links in the chain of its ætiology. The seasonal variation of pellagra as it affected the skin, the digestive and nervous lesions, presented difficulties of elucidation, and was not yet understood. The skin lesions were only a part of the disease, and were known definitely to occur in some cases in parts of the body free from exposure to sunlight or heat, although the typical distribution in portions exposed to their influence were the most common, suggesting the resemblance of the susceptibility of the skin surface to the sensitivity of a photographic plate. In America pellagra, as with beri-beri, was regarded as a food-deficiency disease, and had therefore largely become an economic problem when dealing with numbers of cases, such as 20,000 in the State of North Carolina, and 150,000 in the whole of the United States.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.

A MEETING of this newly-formed society was held on May 17th at 122, Harley-street, Dr. Jane Walker, the President, being in the chair. Twenty-nine new ordinary members and 19 associate members were elected. Dr. H. O. Blanford (Midhurst) and Dr. Vere Pearson (Mundesley) were elected to two vacancies on the executive committee.

Dr. Leonard Hill, F.R.S., opened a discussion on

The Physiological Principles Involved in the Ventilation and Heating of Tuberculosis Institutions.

He first showed that the effects of bad ventilation were not produced by the excess of CO_2 or by diminution of the percentage of oxygen in the air. Workers in submarines could easily stand up to 3 per cent. of CO_2 without discomfort, while in the high Alps the oxygen might fall to 17 per cent. or less without affecting the health of the mountain-dwellers. Similarly the theory that obnoxious organic matter in exhaled air was at fault was exploded. There was the clearest evidence that the physical properties of the atmosphere had a great influence on the physiology of the body, and the determining factors in good ventilation were the coolness, the movement, and the dryness of the air. The drying power of the air was very important, but in measuring it the ordinary thermometer was a poor help. Dr. Hill described his special thermometer, the kata-thermometer, and showed how cool air of low humidity breathed in through the nose is raised to a constant temperature at the back of the nose by means of the increased flow of arterial blood through the mucous membrane. In addition there was a greater flow of lymph which evaporated. These might be increased as much as five or ten times by exercise in the open air. The drier the air, within limits, the better. The greater the vascular activity of the nose the greater was the power of resisting disease; hence the resistance of outdoor workers to respiratory diseases. Apart from influenza, our soldiers and sailors in the war were singularly free from respiratory diseases. The drying power of the skin was of great importance, since through its cooling power the skin controlled the metabolism of the body. Cooling of the skin by outdoor life might double the metabolism during rest, while with exercise it might increase it five or more times, with concomitant improvement of appetite, of assimilation of food, and of elimination of waste and harmful products.

The discussion was continued by the President, Dr. James Watt, Dr. Marcus Paterson, Dr. W. C. Fowler, Dr. Noel Bardswell, Dr. P. W. Edwards, and Dr. Blanford.

In replying to questions and points arising in the discussion, Dr. Hill stated that people should wear as little clothing as possible, and that the temperature of the cheeks largely ruled metabolism. It was the absolute and not the relative humidity of the air which mattered. It was preferable to keep patients indoors rather than to expose them to wet mists. Fans could not be used too much for combating fever in warm weather. With regard to heating, the ideal conditions were to use the radiant heat of the sun. In ordinary dwellings steam-pipes tended to heat the air at the ceiling and to leave the air near the floor as much as 10° colder. It would be better to reverse the position. If the feet were warm, one could stand any amount of cold air. It was not harmful to have different parts of the body under different conditions of temperature. Such differences kept up the nervous tone, avoided monotony, and acted as a stimulant. He commended the practice of many sanatoriums in shutting up and heating by radiators rooms when empty, and later making use of the radiant heat stored in the walls when the rooms had to be opened up for patients. Dr. Hill intimated that the practical questions of clothing and of heating in open-air institutions would be dealt with in a forthcoming publication of the Medical Research Committee.

The President's motion to approach the College of Nursing regarding a remission of part of the period of their general training in the case of nurses trained under proper conditions in sanatoriums was withdrawn in favour of an amendment to appoint a commitee to consider and report on the whole question of the training of nurses for the treatment of tuberculosis.

Dr. Marcus Paterson opened a discussion on

The Relative Value of Butter and Margarine in the Treatment of Tuberculosis.

He believed that in institutions where margarine was used the necessary supply of the fat-soluble A vitamine was quite well obtained from cod-liver oil or from milk, as well as from the animal fats of meat, bacon, and dripping. In most institutions 14 pints of milk were consumed per patient per week, and this contained the equivalent of from 10 to 12 ounces of butter.

The discussion was taken up by Dr. Francis Clark, Dr. Esther Carling, Dr. A. C. Ta'Bois, Dr. W. G. Kinton, Dr. H. E. Watson, Dr. Blanford, and Dr. W. Goodchild. Several expressed the opinion that there was more indigestion with margarine than with butter, but one speaker thought the want of freshness of the margarine was responsible for this. The practice of some institutions in giving butter on Sundays "as a treat" was criticised as inconsistent. On the whole, opinion was strongly in favour of the use of margarine in place of the more expensive butter where milk or cod-liver oil formed part of the dietary of the patient.

Two motions were postponed till the next meeting, one by Dr. Carling encouraging institutions for the treatment of tuberculosis to employ ex-patients upon their staffs being strongly opposed by Sir Henry Gauvain, who was unable to be present at the meeting.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this association was held on May 18th, at 11, Chandos-street, W., Mrs. Flemming, M.D., the President, being in the chair.

Dr. Sibyl I. Welsh read a paper on

The Nervous System and the Endocrine Glands.

She said that Hughlings Jackson had described the development of the nervous system in man as taking place at three levels the vegetative or autonomic, the sensori motor, and the psychic On the *psychic* level, the receptors, through which man receives impressions, are the sense organs of sight, hearing, taste, and smell, and it is through these that he comes into relation with the distant external world By association fibres in the cerebral lobes he gains the power of balancing knowledge with emotion, and intuition with instinct, knowledge and intuition tending to be individual as compared with emotion and instinct, which are racial and shared by his kind At this level he becomes an individual member of a herd On the *sensori motor* level the body has acquired the power of balance and progression through space, coming into contact with externals through the skin receptors of touch, pain, heat, and cold, and acquiring self control through its proprio receptive system, whose centres are in the labyrinth, and through the cerebellum, which receives and coordinates all the impulses of sense of position and movement At this level he becomes an individual, and is able to move about On both the psychic and the sensori motor levels the *controlling nervous mechanism is a centralised one, and control is conscious as well as subconscious* On the *autonomic* level *centralised control is no longer essential* This level governs the most primitive reactions, of nutrition, reproduction, and self defence, and at this point the organism is a mere existence without individuality or sociability In man this level is represented by the mutually antagonistic sympathetic and para sympathetic nervous system, and their working is not merely subconscious, but it is unconscious Developmentally this nervous system is not centralised, and in the lowest vertebrates the place of the sympathetic cells is taken by masses of chromaffin cells In man these cells are chiefly found in the suprarenal medulla, and are derived developmentally from the same mass of cells which gives rise to the sympathetic ganglion This shows how an organ which deals with the chemical type of stimulus progresses into an organ producing the higher type of nervous stimulus, and that below the level of the most simple type of nervous control there is a set of systems of chemical control—a set, in fact, of endocrine glands There is thus a digestive system of chemical control affecting the secreting glands, a reproductive system bringing into functional cooperation the remote sexual glands, and a system influencing growth and development The active principles of the endocrine glands are comparatively simple, and identical for all animals, and in the case of adrenalin it has been prepared by chemical methods outside the body They either stimulate cell activity—the hormones—or depress it —the chalones—and a name which includes both kinds is autocoid

There are three main groups of endocrine glands, the thyro parathyroid group, the suprarenal, and the pituitary *The effects of adrenalin has been most worked out, its action is upon the tissues innervated by the sympathetic nerve-endings only, and not on those innervated by the parasympathetic* Dr Welsh then described the *distribution and functions of the two divisions of the* sympathetic nervous system, stimulation of the sympathetic producing means of defence, and stimulation of the parasympathetic promoting nutrition She referred to the treatment of deficiency diseases by gland extracts, with special reference to cases of slight hypothyroidism in elderly women, and to the increase in exophthalmic goitre since the war She suggested that as there was anatomical evidence of a double control, chemical and nervous, of the endocrine glands, there might be a possibility of a double form of treatment, one form being to restore nervous control by psycho therapeutic measures She gave an instance of an advanced case of diabetes where very striking improvement resulted from such treatment

BRISTOL MEDICO CHIRURGICAL SOCIETY.

AT a meeting of this society held on May 12th, with Dr I WALKER HALL the President, in the chair, Dr. R H. NORGATE read a paper on

The Effects of the War on the Mental Condition of the Citizens of Bristol

The paper was based on a study of almost 3000 patients admitted to his care at the Stapleton and Eastville Institutions during the war The main argument of the paper was that the rate of admission of these patients could be correlated with the rise and fall of mental stress and anxiety occasioned by the course of public events This was illustrated by a series of charts In addition, Dr Norgate showed how the war had coloured the mental processes of the insane One interesting point was the much higher incidence of melancholia in women, a fact which he explained by reference to the peculiarly trying, and anxious, and lonely life led by so many women of the working classes during the war Many lessons of *practical* value for the future were drawn from these war experiences One was the need for sympathetic handling of borderland cases To this end he advocated hospital and not asylum treatment He spoke with warm approval of the work done on behalf of women workers by those who were before the war militant suffragettes Dr Norgate commended work on the land as a means of providing wholesome mental occupation, as work on allotments during the war had had excellent psychic results —Dr L E V EVERY CLAYTON, the President elect, said that to the influences of heredity and stress in the causation of mental disorder must be added that of malnutrition —This remark was expanded by the PRESIDENT in some remarks introductory to the next paper, which was read by Dr J. A NIXON, and entitled,

Famine dropsy as a Food deficiency Disease

Dr Nixon said that famine dropsy had been known for several centuries, and had reappeared in the Great War under various names, such as war œdema and hunger œdema British physicians had met with it chiefly in returned prisoners of war It had been widespread, however, in prison camps in Germany and amongst civil populations where food shortage was acute The first clear differentiation of famine dropsy was made by Cornish, in the Indian famine of 1877-78 But even after that date and well on into the war confusion existed between the dropsies of scurvy, beri beri, ankylostomiasis, and pellagra, as well as cardiac, renal and inanition dropsies The clinical picture of famine dropsy was now clear and might be defined as a form of œdema produced by prolonged underfeeding on a diet deficient in *protein and caloric content, with an excess of fluid* Four cardinal symptoms characterised the disease œdema, polyuria, bradycardia, and asthenia *There was, moreover, a remarkable absence of certain signs and symptoms, namely. albuminuria, cyanosis, dyspnœa, and cardiac dilatation, also the nerve changes of beri beri, the skin changes of pellagra, and the spongy gums and hæmorrhages of scurvy* In the blood and urine there was a hypo albuminosis, with increased ammonia, nitrogen, and kreatin, lipoids were greatly decreased in the blood Post mortem there was a total absence of fat in the body As regards pathogenesis, the whole problem of œdema formation was little understood McCarrison's suggestion that excess of adrenalin might be a factor in the production of œdema in general must be borne in mind It seemed clear that famine-dropsy was not an avitaminosis, and experiments tended to show that it was not due to the absence of a single food factor Dr Nixon drew a comparison between the modes of production of certain food deficiency diseases in the following schematic form —

Scurvy	Beri beri	Pellagra	Famine-dropsy
Deficiency of— Water soluble C Fat-soluble A	Deficiency of— Water soluble B	Protein deficiency + toxin (unknown) + sun-exposure	Calorie deficiency (? fat-deficiency) + protein deficiency + water excess

SOCIÉTE DE THÉRAPEUTIQUE DE PARIS

AT a recent meeting of this society Dr PAUL SOLLIER read a note on the Chemotherapy of Morphinism, in which he alluded to the recent communication by Dr Brissemoret and Dr Challamel, who had suggested a demorphinisation cure by berberine and helenine[1] Dr Sollier maintained that it was a mistake to suppose that substitutes for opium or its derivatives existed All the preparations advertised as substitutes were found on analysis to contain a more or less considerable degree of morphine or a more dangerous derivative of opium

Dr GEORGES ROSENTHAL read a paper on Serum Treatment by the Intratracheal Route preceded by the Formation of a Tracheal Fistula and Intubation The method was carried out as follows After local anæsthesia by intratracheal injection of 2-10 c cm of novocaine and adrenalin, an injection of serum was made either in the intercricothyroid space with a specially curved needle if few injections were to be given and at long intervals, or [illegible] numerous and frequent injections were required [illegible] 1 mm tube and a tracheal fistula In children [illegible] might be performed, and the injections made through the intubation tube The very slight risk of [illegible] be avoided by the use of Besredka's method

Dr MAURICE FOURRIER reported a case of [illegible] *Encephalitis treated by neosalvarsan* [illegible] *girl, aged 17, with typical symptoms* [illegible] *benefit was derived from adm*[illegible] *immediate improvement followed* [illegible] *of 0 30 cg neosalvarsan, and became* [illegible] two more injections. Complete recovery ultimately took place.

---

[1] THE LANCET, [illegible]

In a note entitled "The Site of Election for a Fixation Abscess is on the Arm, Behind the Posterior Division of the Deltoid," Dr. FÉLIX REGNAULT stated that the chief advantage of a fixation abscess in this situation was that the pain was very slight, being less than that of a large blister. This was due to the fact that the injection involved only the terminal ramifications of the cutaneous branch of the circumflex nerve, whereas when the fixation abscess was in the thigh the branches of the anterior crural nerve supplying the knee and leg were affected. Moreover, a fixation abscess in the deltoid region remained localised and did not show a tendency to cause extensive necrosis like the fixation abscess in the thigh.

MONTPELLIER: RÉUNION OBSTETRICALE ET GYNÉCOLOGIQUE.

AT recent meetings of this society the following communications were read.

M. DE ROUVILLE, on the Systematic Scooping Out of the Cervical Stump in Subtotal Hysterectomy. The author urged this procedure, as it presented all the advantages of the total and subtotal operations without the disadvantages of either. The disadvantage of the subtotal operation in inflammatory cases was that an infected cervix was left behind, whilst in fibro-myoma cases malignant degeneration of the cervix is certainly not negligible. M. de Rouville has observed three unpublished cases. By the hollowing-out operation the cervical stump is reduced to a single shell of some millimetres thickness, and all the drawbacks justly attributed to the subtotal operation disappears. The disadvantages of total hysterectomy are the possible risks of sepsis owing to the vagina being opened up and the real risk of hæmorrhage. The operation described by the author avoids these two risks, and he states, lastly, that by this operation the normal anatomical arrangements of the vaginal roof and pelvic floor are not disturbed.

M. VALLOIS described two cases of Pregnancy complicated by Cicatricial Narrowing of the Vagina. The constriction may be "caniculaire ou annulaire," and an anæsthetic may be required for diagnosis owing to the difficulty of examination of these cases. If the narrowing is caniculaire and rigid extraction during labour should be by the abdominal route—Cæsarean section followed by subtotal hysterectomy. The membrane-like annular stricture is easily dilutable, and permits delivery by the natural passages unless there are marked pelvic obstacles.

M. TEDÉNAT discussed Hæmatosalpinx in the light of four cases which he had observed. Although this condition is generally due to tubal pregnancy it may be due to hæmorrhagic salpingitis, as proved by microscopic sections which showed no decidual cells, no cotyledons, and no erosion of the mucosa. Of the four cases reported by the author three were of this variety, and in the fourth tuberculous salpingitis was found.—In the discussion which followed M. DE ROUVILLE described a similar type of case where obstruction of the adnexal circulation was sufficient to explain the condition. Several sections are essential for accurate diagnosis in these cases.

M. VALLOIS and M. MADON read the notes of a case where induction of premature labour was practised for habitual death of the fœtus, a live child resulting. None of the usual causes of this condition could be found, and all that could be detected was a faint albuminuria in the last days of pregnancy. This disappeared rapidly in the puerperium. In the discussion which followed M. VALNALE, after recalling the discordance between certain light and transient albuminurias and their gravity to the fœtus, said that since the war 50 per cent. of the population in certain centres (e.g., Marseilles) suffered from syphilis, and he predicted that in two generations this percentage will be universal.—M. DELMAS urged the importance of examining the father when the examination of the mother was negative. The good effects of treatment confirmed the importance of this line of examination.

M. DELMAS described two cases where blood transfusion was urgently required, and in the absence of special instruments the author utilised the needle of a spinal anæsthesia apparatus with the happiest results. Citrate solution was used to prevent coagulation of the donor's blood. Lubrication of the trocar with vaseline and only allowing citrated blood to flow through the needle prevented coagulation in the needle itself.

NATIONAL COUNCIL FOR COMBATING VENEREAL DISEASES.—The fifth annual meeting of the Council will be held in the Barnes Hall of the Royal Society of Medicine on Monday, June 7th, at 5 P.M., Lord Sydenham in the chair. The meeting will be addressed by Viscount Astor.

Reviews and Notices of Books.

THE PHYSIOLOGY OF VISION.

With Special Reference to Colour-Blindness. By F. W. EDRIDGE-GREEN, M.D., F.R.C.S. London: G. Bell and Sons. 1920. Pp. 280. 12*s.*

THE EDRIDGE-GREEN CARD TEST FOR COLOUR-BLINDNESS. Same publishers. 1920. 25*s.* net.

THE physiology of vision presents several problems as yet unsolved or only partially solved, and this is not to be wondered at when we realise, first, that the relation of the different elements in the minute structure of the retina to the functions that they subserve is still a matter of debate, and secondly, that many of the problems in question—such, for instance, as those relating to binocular vision or those relating to colour contrast—are admittedly psychological problems, the solutions of which depend on the subjective experience of individuals rather than on physical demonstration. To illustrate this the different explanations of what is known as Purkinje's phenomenon may be cited. The phenomenon consists in the variation of the luminosity of different colours according to the brightness of the light in which they are seen, the relative luminosity of red diminishing, and that of blue increasing as the illumination is diminished. Now, according to some observers this phenomenon does not occur if all the rays are cut off save those that are focussed on the macula, and since the structure of the macula differs from that of the rest of the retina in that cones alone without any rods are found there, von Kries has used this argument to support his theory that the rods and the cones represent two different apparatus for the transmission of visual impulses, the one used only in the dark, the other only in the light. Dr. Edridge-Green, however, finds that the absence of Purkinje's phenomenon at the macula does not in all circumstances hold good, and uses his interpretation of the facts to support his theory that the visual purple is the true visual substance, that it is produced by the pigmented epithelium in combination with the rods, and under the stimulus of light is diffused into the fluid which surrounds the cones, imparting to them the vibrations which give rise to nervous impulses.

Dr. Edridge-Green's book is mainly concerned with the problems of colour vision and colour-blindness, and he is now such an acknowledged authority on these subjects that all that he says about them deserves most careful attention. We could wish, however, that the lucidity of his explanations was equal to what we believe to be the essential soundness of his views. As it is, we should recommend any reader of this volume, who is not very familiar with the subject, to have beside him the author's previous work, "Colour-blindness and Colour-perception,"[1] in which much that is somewhat obscure in the present volume will be made plainer. The gist of Dr. Edridge-Green's theory is the removal of the colour-discriminating faculty from the retina, where the theories of Helmholtz and Hering would place it, to the brain, where he postulates a centre for the distinguishing of colour higher up than that for distinguishing form. The number of colours that we are able to distinguish depends on the extent to which this colour centre is developed, the dichromic being able to distinguish only two, and these the furthest apart in the spectrum, the trichromic three, and so on, most of us having arrived at the stage of distinguishing six definite colours, while the exceptional individual is able to distinguish seven. So far the theory is easy to grasp. The distinction is further drawn between "approximate psycho-physical units" and "absolute psycho-physical units," the former corresponding to the number of different colours seen and the latter to the number of absolutely monochromatic divisions seen in the spectrum. The latter units for any individual may be about three times as numerous as the former. This part of the theory is somewhat harder to grasp, but if we understand it aright an

International Scientific Series.

analogy might be made with the sense of hearing. The number of different notes in the octave recognised by the majority of people is 12, and when a song is sung these 12 notes are employed. The musician with a "good ear" is able to tell whether any note is sung truly or whether it is sung too sharp or too flat, and the more highly his sense of hearing is developed the more minute is the difference in tone that he can detect. We suggest that the 12 notes correspond to Edridge-Green's "approximate psycho-physical units," and the total number of differences that anyone can detect by comparing different tones heard in succession to his "absolute pyscho-physical units." However this may be, the psychic theory of colour vision appears to fit in far better with observed facts than either of the older theories. An obscurity which needs explaining is the occasional existence of colour blindness varying in degree in the two eyes of the same individual. Such a case is given with much detail in Dr. Edridge-Green's former book (pp. 196-203), and his theory is obviously incomplete until it is explained. Besides the degree of development of the brain centre, it would seem that there must be some variability in the retinal apparatus by which the light waves that cause the sensation of colour are transmitted as nervous impulses, and that this may be different in the two eyes. Such an explanation is hinted at by the use of the phrase "retino-cerebral apparatus," but it is not worked out. However incomplete the book may be, it is the work of an original thinker, and will be found to be essential by those interested in the subject.

The Edridge-Green card test has been devised to meet the demand for a simple, portable, and comparatively inexpensive test for colour blindness. The wool test, we are told (and the statement can obviously be challenged) has fortunately become obsolete in all important examinations of vision, for not only did it utterly fail to detect more than 50 per cent. of the dangerously colour blind, but also rejected many normal sighted. The principle involved in the card test is the perception of difference between two colours presented in a special diagram of spots of irregular shape and various tones. On a ground of separate spots of one colour a letter is formed in spots of another colour, and each card in the series is specially devised with the object of detecting some special form or degree of colour blindness. The cards are contained in a neat leather case, and form by far the handiest test for colour blindness with which we are acquainted.

PRINCIPLES OF HUMAN PHYSIOLOGY.

Third edition. By ERNEST H. STARLING, C.M.G., F.R.S., Jodrell Professor of Physiology in University College, London. London: J. and A. Churchill. 1920. With 579 illustrations, 10 in colour. Pp. 1315. 25s.

THE second edition, which we reviewed in our issue for July 24th, 1915, is followed by a worthy successor, in which are incorporated such advances as physiology has made during the five years of war. There are to be found a number of alterations, especially in the latter half of the work, and the book itself has been increased in size by 50 pages. The chief changes are in the section on the sense organs, which has been revised and largely rewritten by H. Hartridge, M.A., M.B. Camb., who is entirely responsible for the new section on vision. The domain of physiology has become so extensive that it is difficult for a single author to be master of all its multifarious departments and advances, especially when the calls of war duty have absorbed much of his time. Some of the changes and omissions have resulted in discarding methods of proved utility. The principle of testing visual acuity is laid down, but we failed to find the familiar phrase, "Snellen's test types," mentioned as such in the previous edition. All reference to the phakoscope and Sanson-Purkinje images seems to be omitted. Even Scheiner's classical experiment, as well as the diagram to explain it, seems to have fallen out. The illusions referable to vision are hardly dealt with, and the old familiar Zöllner's lines have disappeared. A simple diagram showing the formation of an image on the retina would be useful. In connexion with the yellow spot, Clerk Maxwell's experiment for demonstrating its existence by means of a solution of chrome alum does not seem to find a place. On the other hand, the causes of night blindness, which has come into prominence during the war, and the theories of colour blindness are fully appreciated and discussed. Holmgren's test with coloured wools is recognised as only of historic interest, and Edridge-Green's lantern is figured and described. As to the numerous theories of colour blindness, the author says, "there appears to be more in favour of Young's hypothesis than is to be found for its rivals. Further than that it is not at present advisable to go." Having regard to the importance of colour blindness in its practical relations to daily life on sea and on land, he rightly adds, "no test can be too searching, and no border-line case should ever be passed; the risk is too serious." As to the theories of hearing, there is a relatively long account and analysis, with the conclusion "it would appear that the evidence in favour of Helmholtz's hypothesis is very convincing."

Among other new matter we notice a mention of Douglas's bag for determining respiratory exchange in man, the "spinal man," "destructive lesions of the cerebellum in man," "diabetes in man," "conditioned reflexes," the very effective exposition of diets, metabolism, the biological value of different forms of proteins and other foodstuffs. Accessory food substances are given the alternative name of food hormones, the term vitamine being relegated to a footnote (p. 694). The "value of alcohol in a diet is entirely that of an accessory or adjuvant in exciting appetite by its taste and smell." The chapters on the heart are both illuminating and practical. Under heart reflexes Goltz's tapping experiment might have been added. On the very practical question of muscular exercise it is interesting to note that the margin of response in normal individuals may be 600 per cent.—i.e., over a moderate period of time the individual may increase his muscular work, his respiratory exchanges, and the rate of his circulation six times above that during rest. Perhaps some more details on the endocrine glands would have been useful, more especially as regards the thymus gland—e.g., status lymphaticus, the pineal gland, and cortex of the suprarenal glands.

Altogether this work is a solid, substantial, and illuminating exposition on quite independent lines of the present state of physiology by one who has added not a few important building stones to the superstructure itself. The whole constitutes a comprehensive and suggestive treatise rather than a mere student's text-book, and will be welcomed both by aspiring students and practitioners of medicine.

CHILD PHYSIOLOGY.

The Principles of Ante-natal and Post-natal Child Physiology, Pure and Applied. By W. M. FELDMAN, M.B., B.S. Lond. London: Longmans, Green, and Co. 1920. With 6 plates and 129 illustrations. Pp. 691. 30s.

THIS is an attempt to give, within the compass of a single volume, a complete account of the physiology of child life from conception to adolescence. It originated, the author tells us, in a course of elementary lectures on child physiology delivered at the Infants Hospital in Vincent-square, where he is assistant physician and lecturer, for he was then led to realise the need for a summary of the investigations published in a host of journals of various languages accessible only to the few. The works of Russians, Germans, Austrians, Frenchmen, Americans, and Italians have been put under contribution, while anatomy and morphology are given a place only so far as these are necessary for a proper understanding of the physical and physico-chemical processes with which the book essentially deals.

The first portion of the book takes up ante-natal physiology, starting from the germinal cells, the nature of hereditary processes, and the at present accepted laws of heredity, leading on to the mechanics of development and a description of the general physiology of pre-natal development and metabolism. The fœtal systems are then taken seriatim, nutrition, circulation, respiration, and so on. Then follow chapters on the physiology of pregnancy, of birth, and of the neo-natal period, with a similar analysis of post-natal functions. A final chapter is devoted to the anatomical and physiological peculiarities of the premature infant.

If the picture is an impressionist one the fault lies with the subject and not with the author. It is, in fact, his peculiar merit that he has defined the limits of our ignorance, which is in ante-natal matters almost abysmal, as well as the limits of our knowledge. Small portions of the subject have been intensively studied, as by Galton, Mendel, Camerer, Baginsky, and Ballantyne, but they scarcely as yet amount to more than oases in vast deserts of unexplored territory. To take an example, the author describes the mechanics of development of the vertebrate ovum through the stages of subdivision in three planes to the blastula and then to the gastrula, changes so far explicable in mathematical terms, only to break off at the stage when certain outgrowths occur which afterwards give rise to limbs and other organs. Here he has to admit our ignorance of what it is that turns the apparent chaos of the germinal globe into the orderly arrangement of the embryonic world. The constraining hereditary force, to use His's metaphor, cannot as yet be expressed in terms of mechanics or physics or chemistry.

Something of the author's industry is apparent from the references, often five or more on a page, to original articles and dissertations in as many languages, and from the index of names, which runs to at least a thousand items. It is good that at the present time, when child welfare work as a social and emotional movement is gaining such momentum, the groundwork should be thus ably set forth on which to build a superstructure of preventive and remedial method with some prospect of success.

A MANUAL OF PRACTICAL ANATOMY.

By THOMAS WALMSLEY. In three parts. Part I., Upper and Lower Limbs. With preface by THOMAS H. BRYCE, M.A., M.D. London: Longmans, Green, and Co. 1920. Pp. 176. 7*s.* 6*d.*

AT a time when books are getting longer, the numbers of subjects increasing, and the time at his disposal getting shorter, the student may welcome an honest effort to lighten his labour by reduction of the amount of printed pages through which he has to find his way in the course of his work. The preface by Professor Bryce indicates the aim of the author of this book to provide a "directory of dissection," with the aid of concise descriptions to guide personal observations. Hence the directions are printed in larger type than the descriptive matter. The aim as outlined is a praiseworthy one, but it is very doubtful if as much can be said for an effort to indicate the amount of knowledge that may be expected from the student, which would appear to be a further aim in the work. There is no item of knowledge in descriptive anatomy which—provided one knows it—may not turn out to be of some practical value in clinical work, to-day or to-morrow or 20 years hence, and experience shows that the fear of any student learning or knowing too much is quite without foundation.

Professor Walmsley's introductory chapter is short but useful and to the point; it might be suggested that a brief account of the use and meaning of fixed terms of position could be added with advantage. The directions and descriptive matter are clearly put, and appear to be adequate for their purposes. It is understood, of course, that the practical work is carried out under the direction of demonstrators, and the description is only a guide to observation, to be extended by fuller teaching. The figures are simple and schematic, and will without doubt prove useful to the dissector. But attention must be called to certain faults in these drawings. Thus, Fig. 6 might give a wrong impression about the attachments of the axillary sheath; Fig. 22 is wrong in essential details; Fig. 41 shows the main vessels out of place and the semi-membranosus partly deficient; Fig. 42 seems to put the insertion of the adductor magnus on the lower part of the articular condyle; and in Fig. 47 the relation between the short extensor and the annular ligament is not that usually found. It is interesting to note that the terminology used is not of the B.N.A., though it is not exactly that of English anatomy: the clumsy "collateral" is used for ligaments, presumably because of the use of the words "lateral" and "medial" in place of the old "outer" and "inner," and practically the only other differences, in the present part at any rate, are to be found in the names given to certain cutaneous nerves. The cutaneous nerves of the upper limb do not seem to be very happily named, and, in the case of the front of the thigh, confusion might possibly arise in the mind of a student whose teachers made use of the older terms of position. Incidentally, it may be pointed out that it is more correct to refer to the angle of Louis than to name it after Ludwig; it is a very small point, but there is no virtue in a Teutonic sound, per se. Although it has been necessary to call attention to certain weak places in the book, it leaves a good impression on the reader, and its simple and clear style, with its practical character, will give it a place among dissecting manuals in everyday use.

OCCUPATIONAL AFFECTIONS OF THE SKIN.

Second edition. By R. PROSSER WHITE. London: H. K. Lewis and Co. 1920. Pp. 360. 25*s.*

OCCUPATIONAL affections of the skin have a legal as well as a medical interest, owing to the inclusion in the schedule to the Workmen's Compensation Act of diseases for which compensation is payable, of dermatitis and ulceration of the skin produced by dust or liquids. Skin affections occur in association with scheduled diseases, such as poisoning by mercury, arsenic, trinitrotoluene, aniline; or as distinct entities, for example, among those who manipulate tar, pitch, paraffin, soot, or chrome. Practitioners working, as the majority do, among industrial populations require definite information as to the occurrence and causation of skin affections which they see in their daily work. In order to meet this need Dr. Prosser White, who had already for many years made a specialty of the subject, five years ago brought out a manual. Apparently, the book met a definite need, as we now have before us a second edition, not only brought up to date, but enlarged, containing several useful new illustrations and much additional matter.

The author has set himself the task of compiling from literature reports upon and references to skin affections of industrial origin. He has amassed a wealth of detail and information, and has then grouped it by occupation. We incline to the view that grouping either by lesions or causation would have been more useful, and would have allowed the author more scope for thought. Facts, however numerous, unless arranged in suitable order, do not advance knowledge; "we must, therefore, form tables and arrangements of instances, in such a method and order that the understanding may be able to deal with them," said Bacon, and his advice should still be heeded. As the book stands, the personality and thought of the author lie hidden behind the facts quoted, and seldom peep through. The book is in consequence rather an encyclopædia of data than a contribution to the elucidation of underlying physical or chemical influences which give rise to similar lesions. An instance may be given. A reader by careful search through the volume may discover that workers exposed to bichromate of potash may sustain: (1) perforation of the nasal septum; (2) characteristic indolent and painful ulcers on the knuckles and sides of the finger-nails; and (3) erythema and dermatitis of exposed areas of skin; and that common salt, lime, arsenical and other compounds can give rise to exactly similar lesions. He may be led to cogitate as to whether these similar lesions represent similar reactions on the part of the tissues affected to the agencies concerned, as to whether each agent possessing marked hygroscopic properties may not exert its influence by depriving the tissues of moisture, and as to whether he may not expect to find similar lesions from exposure to other hygroscopic substances.

The author of the book under review will give no aid here, he is content to state the facts and to suggest remedial treatment

Modern medicine with its development of prevention seeks for generalisations, and we regret that a book compiled with such labour, and dealing with occupations where prevention is, comparatively speaking, easily attainable, should not deal with underlying principles We have already mentioned that occupational dermatitis has a legal as well as a medical interest, but we are astonished that Dr Prosser White has omitted all reference to this side of the question Brought in contact as he must be in his daily work with compensation cases, his experience of the working of the Act, of its advantages and disadvantages, would have been of great interest and value to others Further, an exposition of the law would have been of great help to busy practitioners meeting with cases, but ignorant as to how to proceed in the interest of their patients Nevertheless this book must prove of great value, if only as a key to the literature of an interesting branch of industrial medicine, it is to day the only book dealing with this subject

LECTURES ON VENEREAL DISEASES

By LEONARD MYER, F R C S London Albany Press 1919 Pp 88 6s

THE educational schemes which have been initiated in order to instruct the public with regard to the nature and dangers of venereal disease have been many and various The literary output dealing with venereology from the professional point of view has also been a huge one There exists however, an intermediate and most important group of individuals for whom a comparatively small provision has been made, we refer to those who, although not members of the medical profession, yet do not belong to the ordinary lay public, such as nurses, midwives, masseurs and others who are intimately brought into direct contact with these diseases in the pursuance of their professional avocations It is important that such persons should possess a wise and proportionate view of the subject, together with a clear idea of their own limitations Lectures have been given in various hospitals to nurses on this subject, but we are convinced that there are large numbers engaged in private nursing or employed in nursing homes who have never had the opportunity of attending any such courses It is not remarkable, but much to be regretted, that an ignorant and unsympathetic attitude is assumed in many instances

We heartily welcome Mr Myer s endeavour to deal with this difficulty He exhibits a due sense of proportion, an interesting style, and a clear method of exposition We recommend his book confidently to members of the classes to which we have referred But if he had treated the two diseases gonorrhœa and syphilis separately it would have been an advantage And in another edition we hope the author will see his way to writing with even a greater degree of insistence upon the extent and dangers of ophthalmia neonatorum A slip has been made as regards the relation of the peritoneum to the posterior wall of the uterus on page 30, which will no doubt also be corrected in a new edition The book is certainly deserving of success

DIE THERAPIE DER HAUT UND VENERISCHEN KRANKHEITEN

Mit besonderer Berucksichtigung der Behandlungstechnik fur Arzte und Studierende By Professor Dr J SCHAEFFER (Breslau) Vierte vermehrte und verbesserte Auflage Berlin Urban und Schwarzenberg 1919 With 67 illustrations in the text Pp 485 M 22

AN excellent book, written for practitioners and students this is a collection in book form of a series of articles, most of which appeared in the "Medizinische Klinik," and of notes written for post graduate courses The author is quite right in laying great stress on correct technique in the treatment of skin and venereal diseases, and in the first few chapters deals with the subject in a clear manner, giving full details at the same time Abundant and distinct illustrations are most helpful in demonstrating the practical application of the directions given in the book The skin diseases are treated alphabetically, a fact that makes it easy for the practitioner to find his needs

It is surprising that diathermy and radium treatment, which of recent years have become so important, have been dealt with but casually, whereas X ray treatment and the application of actinic light are fully discussed The last two chapters (150 pages) are devoted to venereal diseases In the diagnosis of syphilis no mention is made of the Congo red method, which has been proved to be superior both to Burri's method and the staining method of Giemsa Although the author has greater faith in vaccine therapy than the majority of German authors, he has seen no benefit from this treatment in uncomplicated gonorrhœa, which is contrary to the experience of many observers In complications such as prostatitis, epididymitis, arthritis, vaccine treatment has apparently yielded very good results in his hands

Throughout the book many prescriptions are given, the price being mentioned also That it was written during the war is apparent from the fact that substitutes for the prescriptions are frequently indicated A useful discussion on marriage consent after gonorrhœa and syphilis will be found at the end of the chapters on these diseases The fact that there have been four editions within four years is proof of its usefulness

WITH THE 1/1ST LOWLAND FIELD AMBULANCE IN GALLIPOLI

By G H EDINGTON, M D, D Sc, Colonel A M S (T F) Glasgow Alex Macdougall 1920 Pp 72

THE WORK OF V A D LONDON NO 1 DURING THE WAR

Edited by STANLEY UNWIN London George Allen and Unwin, Ltd 1920 Pp 96 5s

THE sharing of new experiences is provocative of authorship, and the histories of various units, which have lately appeared, are of vivid interest to the members of the units themselves and sometimes to those outside the focus of experience Colonel Edington writes the history of the 1/1st Lowland Field Ambulance which left England on June 5th 1915 landed at Helles on the night of June 27th 28th and stayed there until the final evacuation of the Peninsula on the night of Jan 8th 9th, 1916, a six months record of useful work with the usual alternation of excitement and drudgery

The work of the V A D No 1 was necessary and valuable, and for that reason has a claim to reward Mr Unwin s lucid account of its doings may help in drawing attention to a branch of Red Cross activities which escaped much public notice at the time

PHYSICAL RECONSTRUCTION AND ORTHOPÆDICS

By HARRY E STEWART, M D, Captain, M C, U S Army, Division of Orthopædics, Assistant Director, Section of Physiotherapy, Surgeon General s Office, &c New York Paul B Hoeber 1920 Illustrated Pp 275 $3 75

THE author describes this book as a condensed manual Baking, hydrotherapy, and electrotherapy, being taken together, are only awarded 19 pages while "massage" is disposed of in 33, including, in both cases, the free use of illustrations It follows that the matter thus condensed is very elementary The second part of the book which deals with orthopædics, is equally condensed, and many important points are omitted In the treatment of sacro iliac strain, for example, no reference is made to Goldthwait's extensive and valuable work, and we look in vain for advice as to the treatment of Colles s fracture and of fracture dislocations of the ankle after the stage at which deformity has been reduced A chapter on foot strain is, however, a marked contrast to the rest of the book (it occupies 24 pages), and is far the most useful part of the work The book will indicate to those uninitiated in physical therapy the possibilities of treatment, it will not guide them in prescription or performance. The illustrations are, for the most part, excellent, but those showing the electro-motor points (after Pariset) are lacking in clearness.

JOURNALS.

British Journal of Experimental Pathology. Editors: C. H. BROWNING, P. FILDES, W. E. GYE, E. L. KENNAWAY, E. H. KETTLE, J. MCINTOSH, J. A. MURRAY, W. J. TULLOCH, C. M. WILSON. London: H. K. Lewis and Co., Ltd.—The second number of this journal reaches a very high standard of excellence, upon which the contributors and editors are to be congratulated. If the same standard can be kept up, British contributions to pathology will have nothing to fear from comparison with the work of any other country. As will be noticed in the short summary of contents given below, the first critical review of a pathological subject is included in this number. The subject chosen is influenza, and we can think of no other condition more in need of critical examination.—The Value and Mechanism of the Colloidal Gold Test, by J. Cruickshank, M.D. This article is a timely contribution to a subject of great importance, upon which a considerable amount of work has been done, chiefly in Germany and America. The test is applied to cerebro-spinal fluid in cases of suggested syphilis of the central nervous system. It owes its origin to the work of Zsigmondy upon the influence of electrolytes on colloidal gold and the "protective action" of colloids. Lange applied Zsigmondy's work in testing the protective powers of normal and syphilitic sera, and later of spinal fluids. It was found that spinal fluid from cases of dementia paralytica has the property of precipitating the colloidal gold, and it is this reaction which has been recommended for diagnostic purposes. Dr. Cruickshank, who has evidently worked for some considerable time at the question, reviews very thoroughly the literature of the subject, describes how to prepare the reagents employed, and particularly the colloidal gold, and, basing his conclusions upon his own work, states that the "results of the colloidal gold test coincide with those given by the Wassermann reaction." There is evidence, however, to show that the gold test is the more delicate. The substance in the spinal fluid which reacts with colloidal gold is not dialysable and resides in the globulin.—The Experimental Transmission of Encephalitis Lethargica to a Monkey, by J. McIntosh and H. M. Turnbull. The authors give an account of the successful transmission of encephalitis lethargica to two monkeys. One animal was injected with an unfiltered emulsion of pieces of spinal cord and brain of a fatal human case of the disease, and the second with a filtered emulsion. The first animal was killed three weeks after inoculation, when it was in a drowsy condition. The second animal died two months after inoculation after an illness lasting, with remissions, seven weeks. The histological examination of the central nervous system of this animal is given in great detail, and beautiful figures are shown to illustrate the main lesions. There can be no doubt that the authors have been successful in transmitting the disease with material which has passed through a Berkefeld candle.—Conditions which are Conducive to the Production of Shock by Histamine, by H. H. Dale. The author shows in this paper that whereas histamine can be given intravenously to a cat in doses up to 10 mg. per kilo., without any severe or lasting effect, in animals under ether anæsthesia 1 to 2 mg. per kilo. produces fatal "shock." A large hæmorrhage similarly reduces an animal's resistance to histamine. Anæsthesia produced with nitrous oxide and oxygen does not lower the resistance to histamine.—The Comparative Oxygen Avidity of Normal and Malignant Cells Measured by their Reducing Power on Methylene-Blue, by A. H. Drew, D.Sc. It was shown by Ehrlich in 1886, in a classical experiment, that fresh tissues possess the power of reducing methylene-blue to its colourless form. Dr. Drew has utilised this reaction to compare the oxygen avidity of tumour cells with that of normal tissues. His method of procedure is to mince up the tissue and place the mince in a very dilute solution of methylene-blue in Locke's fluid, incubate at 37° C., and then to read at intervals the length of column decolorised. It is found in this way that normal cells are much more active reducers of methylene-blue than malignant cells. Of normal tissues kidney is the most active, followed closely by testis. The embryo is intermediate between normal and malignant tissues. The reaction is not obtained when the cell is killed by freezing and grinding, thus showing that the phenomenon is not entirely dependent upon an enzyme.—The Ætiology of Influenza, by Paul Fildes and J. McIntosh. This is the first instalment of a critical review of the subject. The authors have chosen, and we think with advantage, to analyse the basis upon which we may legitimately conclude that an organism is the causal element in any given disease. Koch's postulates, which have been accepted for thirty odd years as the guiding principles in this matter, were not, it appears, ever definitely formulated by Koch. In their historical inquiry the authors have had the advantage of consulting Professor William Bulloch, whose knowledge of bacteriological and pathological literature is unrivalled. It appears that Henle was the first to recognise clearly that, in order to prove that a given formed element in a lesion is of causative significance, it is necessary to isolate the element and test its powers. This, however, is by the way, and serves as introduction to the serious consideration of a vital and very difficult problem. The three main conditions which an organism should fulfil, if it is to be established as a causative agent of disease, are:—

> (1) The virus should be capable of being recognised in a large proportion of the cases of the disease, preferably in relation to the chief lesions; (2) the virus should be shown to be living; (3) the virus should be shown to be capable of reproducing the disease in other animals.

These three rules are critically discussed and their application illustrated by reference to "modern instances."—In the section devoted to technique S. L. Baker describes a method for the demonstration of the capsules of bacteria, depending upon the use of Indian ink; and P. Fildes gives the formula for the preparation of a medium for the cultivation of *B. influenzæ*.—The journal is well produced, well printed, and of a handy size. It deserves the whole-hearted support of the profession.

Tubercle, a Monthly Journal Devoted to all Aspects of Tuberculosis, Vol. I., No. 8, May, 1920.—In a leading article Dr. J. B. McDougall puts to the test of war experience the belief that pulmonary tuberculosis is induced by trauma of the lung. Excluding six cases whose pre-existing lung disease does not seem to have been aggravated by the wound, only one out of a total of 139 cases of penetrating wound of the chest subsequently developed pulmonary tuberculosis, and several authors are quoted as recording similar results. In fact, if the trauma had been fractured femur instead of injury to the lung the proportion affected by subsequent tubercle could hardly have been less. No doubt patients with trauma of the chest have often been condemned as tuberculous owing to the ambiguity of physical signs, for Dr. McDougall points out that "no sign or symptom of phthisis may not be simulated by a foreign body in the lung if an examination of the sputum be neglected." X rays are, of course, valuable, but not infallible. A very interesting little research on the incidence of tuberculosis in an isolated Norwegian village has been carried out by Dr. Björn-Hansen. Tuberculosis of the skin is the subject of a number of abstracts of recent articles on the numerous forms of these affections, covering no less than nine pages. Among other articles a detailed account of tuberculosis administration in Edinburgh is worthy of special notice by practical workers.

Paris Médical.—The French medical press is occasionally enlivened by articles on the historical or artistic aspects of medicine. The issue of the *Paris Médical* for May 1st contains some interesting Notes on the Measles of Lous XIV., by MM. A. Gilbert and P. Cornet, in which the authors, besides giving the history of the monarch's illness, quote St. Simon's remarks on his prodigious appetite, and the poem on the King's convalescence, written by Racine, which gained for the poet his first presentation at Court.—The same number has a delightful article by M. Malorey on the Monastery of the Val de Grâce up to the death of Anne of Austria. Few people who visit the Val de Grâce Military Hospital realise the antiquity of the buildings whose foundation-stone was laid by Anne of Austria in 1624, and M. Malorey has evolved not only the ulterior history of the original building Le Petit Bourbon, but the tale of the Queen's difference of opinion with her architect Mansard, and many other historical items sandwiched between philosophical reflections. The pathological side of art has always interested doctors, and, in *Paris Médical* M. Henri Roché discusses the Salon de l'École Française from the medical point of view with a genial indulgence that dwells on the good intention rather than on the feeble accomplishment. His note on one of a series of pictures by M. Prévot, designed for the musée of the Val de Grâce is an example of his kindly criticism. The painting is called "The Wounded of the Val de Grâce Taking Refuge in the Cloister during the Bombardment of Paris," and M. Roché says of it: "This composition is rather confused, but suits the subject; if the story attracts us the perspective and the lighting are less defensible." The sight of a number of nude women painted one blue, one violet, one red, and one yellow, by the same artist, only draws from M. Roché the mild comment that he must have frequented hospitals too much to be able to see clearly! The picture of a pre-human family called "L'Age de Pierre," by Riolet, seems to have somewhat strained M. Roché's lenity, but after noting the strange resemblance of the male to the late Francis Joseph and describing the picture, he can only bring himself to say, "And to think that there are such beautiful subjects for painting without going back to prehistoric times!"

THE LANCET.

LONDON: SATURDAY, MAY 29, 1920.

The Future of the Medical Services: The Report of the Consultative Council.

WE publish this week a full abstract of the Interim Report on the Future Provision of Medical and Allied Services which has been made by the Consultative Council on these Services to the Ministry of Health. The Report is signed by Lord DAWSON OF PENN as Chairman of the Council, and Colonel C. J. BOND as Vice-Chairman, on behalf of the Council, whose personnel we recall to memory in our abstract. It may be taken therefore that the Report, rendered by a trusted group of experts, is a unanimous one, though it stands to reason that where so many difficult and even contentious points have been in question the unanimity must have been arrived at by a considerable adjustment and readjustment of personal views. This is exactly as it should be, having regard to the significant note of introduction from the Minister of Health, and the deliberately loose reference to the Council. Dr. ADDISON points out that the Report has been published to facilitate discussion, having in view, no doubt, the impending Health Services Bill. What, therefore, the Minister of Health expects from the Report is general guidance in the framing of a large measure which will inevitably receive many modifications between the stages of its inception and its final enactment. Here the Report should be of real utility, for, having many polemical subjects in review before them, the members of the Council have come to certain common conclusions, by acceptance of which time will be saved in the future discussion of health matters. Moreover, the profession and callings concerned, and the public, are asked to study the Report, and thus help by their criticism to obviate differences of opinion, as far as may be, at an important stage of public health affairs.

The scheme laid down in the Report is quite a detailed one, the space that might have been occupied, perhaps fruitlessly, by recounting the arguments which led to the conclusions, being taken up more practically with the setting out of the steps of reform and the development projected. It is clear to all engaged in public work that the scheme cannot be set in motion at once in its entirety, however much goodwill on the side of the public and on the side of the medical profession may lie behind it, because considerable changes are postulated in the existing law, and a great expenditure of public money is assumed; yet trial along many lines, to see how far it furnishes a practical solution of public and professional difficulties, appears quite possible. Indeed, as Dr. ADDISON points out in his foreword, action is already being taken by the Ministry of Health and the local authorities in relation to many matters touched upon in the Report. The document seems to us, therefore, both in scope and temper, much what might have been expected from the Consultative Council, which was asked to give expert advice as to the systematised provision of the services in question, to be applied to a given area. The recommendations will have to be considered in relation to a comprehensive policy, but in their general bearings, as they apply to a given area, their justification in that area should lead to natural rivalry in other districts. Thus State help could be directed by the local successes, and could be applied elsewhere, and in a wider manner. For it will not be forgotten that the Report is an interim one, it being clearly the intention of the Council to follow up its recommendations by advice to be given, when and where needed, for the extension and development of health services. It is right to lay stress on the interim nature of the Report because of the promises of work and the opportunities of its revision which are conveyed by the term. While the scheme for the future of the Medical and Allied Services is symmetrical and clear, it would be perfectly easy to raise questions as to the practicability of this or that suggested move. But it would be difficult to find places where the problems, as stated, are not the logical derivatives of facts familiar to many of us. In its broad outline the scheme supplies that proper intercourse between centre and periphery which has been notoriously absent from the health services of the country. In this way it is itself representative of the very sentiments which, by their insistence upon the need for a unifying and directing force in public health affairs, led to the institution of the Ministry of Health. The Report will be on sale through any bookseller, or directly from the Stationery Office, and although we have found room to publish an abstract which reproduces its essentials, we urge upon all our readers the necessity of consulting the actual document. All will remember how the overwhelming evidence in regard to the multiplicity of central departments and of local authorities brought about the Ministry of Health, if only as a remedy for such anomalies; and we need not recapitulate the glaring examples supplied by numerous witnesses of the comical overlapping and intricate complexity of health administration which led to the new legislation. But what has to be remembered is—and strange it is that it should be forgotten—that the Ministry of Health arrived when the country was plunged in war, and that the processes of evolution were all immediately complicated, and some for ever suspended. Nor can it be said that the circumstances for the orderly working out of our sanitary salvation are yet in the least promising, while the effects of the war still hinder public work in every direction. But this interim Report is a practical step forwards; it is a piece of direct assistance to future legislation by its suggestions for the removal of the complications and absurdities of the past and for giving effect to a better state of things.

Preliminary to the presenting of the Health Services Bill to Parliament the Ministry of Health has thus received from its Consultative Council advice, ideal in scope and detailed in design. We may state at once our belief that with the general spirit of the Report, saying nothing whatever as to its practicability as a whole, the members of the services concerned will be in considerable agreement. Those desirous of a whole-time State service will be disappointed that their beliefs are not adopted, but the suggested extension of duty, which will carry with it State or municipal pay, shows that their reading of the facts of professional life has received close attention. Those who, in defiance, as it always seems to us, of the finer and more economical course, have insisted upon the early death of the voluntary system in our hospitals, will find in the scheme proposals for the immense improvement of that system, if generously supplemented in the indicated directions. This may be read as acquiescence in many of the arguments of those who oppose the voluntary system, being a confession that much outside help is required if that system is to be maintained. While the medical profession, in the Report, is regarded as a whole chain, the separate divisions have received symmetrical attention, each link being appraised. The connexion between the general practitioner, the consultant, the specialist, and their auxiliaries, as well as the actual ways in which domiciliary and institutional treatment affect each class, have been thought out, and the scheme has been evolved with broad expectation of better things. In a score of places there is room for the discussion, which the Minister of Health asks for, which the Consultative Council expects, and which reference to the columns of the medical press will forecast. For the scheme, while new in setting and executed with the free brush of those who paint ideally, is in many respects on all fours with schemes which have been before the medical profession for some time. It is no *pastiche*, but the Consultative Council will certainly not sacrifice the value of heredity by suggesting that its plan has not had worthy ancestors. Reform has been proected along similar lines for many years, notably by the British Medical Association, whose scheme or the establishment of hospitals, clinics, and treatment centres for different areas has much in common with the scheme of the Consultative Council when dealing with institutional treatment. To unify our profession, and to make the reatment for all assume the standard which reedom of thought and of action alone can give, has been the underlying idea of the Report, and to give expression to this idea, is the duty of the Consultative Council.

We publish also this week a summary of the First Report of the Welsh Consultative Council. It will be seen how far it is in general agreement with the English Report, and economists will rejoice in the evidence which it produces that much of what has to be done is already in the active doing. The particular significance of the Welsh Report is that it emanates from a composite body, so that one document puts forth the views alike of the representatives of the Medical Profession, of the National Insurance Commission, and of Local Medical Administration.

Opium, the Treaty and the League.

NOT a little confusion exists in the minds of some who have attempted to follow the respective provisions of the International Opium Convention of 1912, the Versailles Peace Treaty, and the League of Nations Covenant in regard to the restrictions it is sought to place upon the traffic in drugs of addiction. It may be well to endeavour to elucidate the present position to which this international effort to check the illicit use of opium, morphia, cocaine, &c., has now attained. In 1911–12 a diplomatic Conference was held at The Hague, at which the representatives of some dozen Powers collaborated in drafting an international convention for the limitation of the use of these dangerous drugs to legitimate and medical purposes. The Indo-Chinese trade in opium, which had received the unanimous condemnation of the House of Commons in 1906 as "morally indefensible," petered out, under an agreement between Great Britain and China, in the year 1917. But at a Commission held in Shanghai in 1909 it had already become clearly evident that the so-called opium evil was not a question of the Far East alone, but that in the form of addiction to morphia, heroin, and cocaine the Occident as well as the Orient had its narco-maniacs, and that any measures for meeting the evil must be world-wide in the extent of their operation. The United States had come to recognise that not only was this question an affair of theirs in their Philippine possessions, but that "a serious opium evil obtained in the United States itself."

The Convention drawn up at The Hague in 1912 aimed at the international control of traffic in opium, whether raw or "prepared" for smoking or medicinal use, morphia, heroin, cocaine, and their respective salts, and the regulation of the production, sale, distribution, or possession of these "dangerous drugs" through legislation and administration by each of the contracting parties. Its effectuating clauses provided for the signature and ratification of the Convention by all Powers, in addition to those represented at the Shanghai Commission and The Hague Conference, for the coming into force of the Convention and for the enactment of the legislation which adhesion to the Convention involved. Two subsequent conferences at The Hague, in 1913 and 1914, the last just before the outbreak of war, were able to record considerable progress in securing the adhesion of some 44 Powers to the Convention through the intermediation of the Netherlands Government. Moreover, at the third and last Conference a special protocol was devised for signature by such of the Powers as had already ratified the Convention and who were prepared to take action without waiting for the other Powers to come into line. The five years of war of course put an end for a time to any such international coöperation as the effectuation of the Convention implied. When peace came the threads were again taken up, and by Article 295 of the Treaty of Versailles those signatories to that Treaty who had hitherto not signed or not ratified the Opium Convention were held to have both ratified the Convention and signed the special protocol to which allusion has just been made. Thus Germany, which had in June, 1914, refused to ratify, was brought into line with Powers such as the United States, the Netherlands, China, and Norway, which had both ratified the Convention and signed the special protocol. The same article of the

Versailles Treaty required the enactment of legislation in accord with the provisions of the Convention within 12 months from the coming into force of that Treaty. This date has since been fixed as Jan. 10th of this year, so that before Jan. 10th, 1921, legislation by the contracting parties should have been passed.

From an answer recently given in the House of Commons the Government appear to hold that Great Britain, although she had ratified the Opium Convention prior to the war, is covered by the terms of Article 295 of the Peace Treaty, and is bound to enact the required pharmacy legislation this year, as well as to observe the provisions of the special protocol. In furtherance of this undertaking the Home Secretary on May 4th introduced a Bill entitled the "Dangerous Drugs Bill," to give effect to the International Opium Convention of 1912. It contains stringent clauses forbidding, under heavy penalties, the import or export of "prepared opium" for smoking, restricting the import, export, sale or distribution of raw opium to licensed or authorised persons, and regulating the manufacture, sale, possession, and distribution of morphia, cocaine, &c. Recent disclosures in police and coroners' courts have directed attention to the range and extent of the illicit traffic in these drugs of addiction. It is not creditable to learn, as the President of the Board of Trade stated on May 17th in the House of Commons, that more than 300,000 ounces, valued at over £300,000, of British-made morphia were exported last year from this country. Sir R. HORNE's statement will be found in our Parliamentary Correspondence this week, and it must be remembered that particulars are not available of exports through the post. It is alleged that no inconsiderable portion of this drug finds its way through Canada and the States to Japan, and thence to China. It is, indeed, cynically averred that while Indian opium has been shut out of China British morphia has been going in, and Dr. WU LIEN TEH, at a medical conference at Peking recently made grave charges in this respect against certain of our manufacturers. There can be but little doubt that the world-supply of opium and morphia is grossly in excess of any conceivable legitimate use. The area under the poppy in India has, moreover, shown a remarkable rise between 1913 and 1917, as will be seen by the tabular statements circulated by the Secretary for India (see p. 1199); and though the export trade from India to China is said to have ceased, some 10,000 chests of opium were in 1918–19 exported from India, chiefly to Indo-China, Japan, Java, Siam, Hong-Kong, and Straits Settlements.

It was the object of those who drafted the Opium Convention to control at the source the fabrication of these drugs, so that, while placing no impediment upon their legitimate and beneficent medical employment, their prostitution to vicious abuse should not be fostered and maintained by an over-production which must inevitably lead to illicit consumption with its attendant social and moral degradation. It is to be hoped that the League of Nations, to whom the international carrying out of the Opium Convention has been entrusted, will lose no time in promoting legislation on lines similar to those of the Home Office Bill, by all those Powers, nearly 40 in number, which have entered into its membership. Here is a piece of humanitarian and social reform ready to hand by the promotion of which the League may well earn the gratitude of mankind.

The Prophylaxis of Shell Shock.

IT is possible that with the spate of articles, monographs, books, and reports on the question of "shell shock" during the last few years the profession may feel there is little new to be learned about it in these days, and it is, perhaps, natural some should be inclined to give the whole subject a rest. Nothing was too good for the wounded fighting man in his hospital and convalescent days, but mufti is less appealing than uniform, blue or otherwise, hence the pathetic figure standing forlorn outside a public-house, with a stringed instrument in his hands, and "Another Pensions Scandal" in large letters on a chest card, fails, apparently, to arouse even a languid interest. Possibly "shell shock" lost caste when it was shown to be little else than a banal traumatic neurosis, so facile are certain minds to be intrigued by the unusual, so prone to be bored by the commonplace; but there is a pathos of the commonplace none the less, which should rouse to action all of us for whom, in STEVENSON'S words, pity is no longer an emotion, but a motive.

Little, indeed, would be the advance made in our knowledge of the psycho-neuroses of war were it to be confined to reparation, or were the half expressed belief that Armageddon will never return to result in the dismissal of the question of possible prevention of "shell shock" from the field of practical medicine. It has not infrequently happened that fertile suggestions for the furtherance of some professional problem have emanated from the intelligent lay mind, which surveys the subject from a different angle and may be conversant with some aspect less likely to be familiar to the medical. In this connexion we wish to direct attention to the recent discussion in the House of Lords on Lord SOUTHBOROUGH'S motion for an expert inquiry into all the phenomena of "shell shock," and to the valuable expressions of opinion to which that discussion gave rise. Hitherto little or nothing has transpired in public as to the occasional occurrence of grave dereliction of military duty on the part of some of our combatants, who because of what in military law is termed desertion or cowardice paid the extreme penalty. According to Lord HORNE it was rather "in the later part of the war" that the possibility of the military crime being due to some or other form of psycho-neurosis led to the accused's coming under the surveillance of medical authorities or being detained for observation. The implicit deduction is, we fear, that there were tragedies in the earlier days on which we do not care to linger. Probably some practising neurologists saw cases here at home of officers who had been adjudged incapable of leading men or unfit for professional duties, who left the service under a cloud or were reduced to the ranks, officers who, as a fact, were suffering from what the old school called "funk," but the new, traumatic psycho-neurosis. It took time for the novel conception to filter through to the administrative strata of the military machine, and we find ourselves in agreement with Lord SOUTHBOROUGH'S contention that the disorder now called "shell shock" must have occurred in other wars, and that among its victims were many whose condition was never properly understood. We are irresistibly reminded of the civilian victims of *la grande névrose*, whose tragic deaths dotted the sixteenth and seventeenth centuries.

On the other hand, however, decision as to motives is a task to try the most expert psychologist, and if the general trend of recent opinion is that responsibility may be abrogated through mental disturbance causing the loss of control, there is danger, nevertheless, in a loose humanitarianism. The safeguards which Viscount PEEL stated were set up in the procedure of courts martial doubtless served their purpose, judging by the contrast between the figures of the condemned and of those who actually underwent the extreme penalty. But all, or at least a good part, of this painful business might be obviated in the warfare of the future were it possible in some degree to prepare the mind of the fighting man against the disasters of hysteria or other traumatic psychoneurosis. Is such a proposal feasible? Though schools innumerable at home and behind the fronts familiarised the young soldier with the conditions of actual warfare they could not reproduce the sights and sounds and smells that would subsequently bombard his sense avenues till his receptors either failed to convey more impressions, or their heightened sensitiveness resulted in overwhelming of his centres. Dr. MORTON PRINCE has suggested that confidence might be imparted by training and education, so that the soldier, forewarned as to the influence of his own fears and of external stimuli, might be in some degree forearmed. This is a matter for serious investigation. In the welter of fighting two great emotions are apt to rise into consciousness to mould conduct—hate and fear. The latter takes origin largely in the unknown, the unforeseen, the uncontrollable; when relatively stable and familiar situations are destroyed and we are projected into situations with which we are no longer familiar, we may react with fear. One aspect of the training problem, therefore, might be to accustom the recruit to the novelty of war environment, as far as such an attempt can ever be realistic; but it would be of greater significance to ascertain of what stuff he *is* made. During the war it became apparent, we think, that there were two types of nervous breakdown: some men collapsed within a period of actual fighting, measured merely by days or even hours; others "stuck it" for years ere their current of nervous energy began to ebb. Some preliminary psychological examination of the recruit might help to segregate the potential neurotics from the others, though it must be admitted that in actual fact hysteria occurred where it was least expected, while especially among the flying men the hypersensitive proved superior to the phlegmatic.

The difficulties which suggest themselves ought not to deter the authorities from obtaining a consensus of expert opinion on the pathogenesis of "shell shock" from the point of view of its subject. Even as early as December, 1914, we drew attention to the fact that traumatic hysteria was showing itself in men who admitted they were in excellent physical condition when the incidents precipitating the neurosis occurred, but nothing whatever was known of their psychical "make-up." So exhaustively has the subject been studied that we conceive all the material is at hand for a thorough examination less of the external factors than of the internal; knowledge derived from such an investigation is the essential preliminary to the elaboration of any scheme of prophylaxis. It is a task demanding the services of men of the highest eminence in this particular branch of investigation, and we should await the report of such a committee with keen interest.

Annotations.

"Ne quid nimis."

NATIONAL HEALTH INSURANCE BILL: CHANGES IN BENEFITS AND CONTRIBUTIONS.

THE National Health Insurance Bill, which has just received the Royal Assent, makes important changes in the benefits and contributions under the Health Insurance Scheme to operate from July 5th next. The object of the changes is to provide for an increase in the rates of benefits in view of the fall in the value of money. The normal rate of sickness benefit will be raised from 10*s.* to 15*s.* a week in the case of men, and from 7*s.* 6*d.* to 12*s.* a week in the case of women; disablement benefit will be raised from 5*s.* a week to 7*s.* 6*d.* for both men and women; and the amount of maternity benefit will be raised from 30*s.* to 40*s.* In order to provide for the increase of benefits the joint weekly contribution is to be increased from 7*d.* to 10*d.* in the case of men, and from 6*d.* to 9*d.* in the case of women, of which the employer's portion will normally be 5*d.* in each case. In certain cases where low wages are paid the employer will pay a larger and the worker a smaller portion of the joint contribution. The contribution cards from the week beginning July 5th next must in all cases be stamped at the rate of 10*d.* a week for men and 9*d.* for women; stamps of these values will be on sale at post-offices.

MEDICINE IN CHINA.

THE medical profession is essentially a fighting service, engaged in a continual warfare against disease. Wherever sickness or wounds are worst, there is the spot for the doctors to concentrate. The recent war provided an example of which we may well be proud. Few of us, perhaps, think of China as a point for such concentration, yet probably no country in the world presents a greater challenge to medical science or a larger field for patient labour and for original research. In the forefront of those who have sought to meet this challenge we must unhesitatingly place the missionary doctor. In proportion to the need his efforts may seem grotesquely small. We read in Dr. H. Balme's recent inquiry into the scientific efficiency of mission hospitals in China that there is still an average of only one mission hospital bed to every 26,640 people in China, and that 80 per cent. of the hospitals have only one foreign or foreign-trained doctor. Certainly there is scope enough for improvement here. But it is gratifying to know how much has been done. To many of our readers Dr. Wu Lien Teh's article (see p. 1203) will come as a surprise. The advance made in nine short years can probably not be paralleled by the experience of any other country in the world. The romantic story of the fight with pneumonic plague in Manchuria in 1911 has been told before. Not only had this far-reaching effects in checking the scourge and saving, it may be, the whole of China from invasion, but it provided an object-lesson in Western medical science that the Chinese were not slow to learn. From that beginning, with characteristic thoroughness and enthusiasm, the medical service of China was organised. What has already been accomplished is a notable page of medical history, briefly summarised in Dr. Wu Lien Teh's article. The coöperation of Chinese and foreigner in this advance has been one of its most notable features. We feel that Chinese medical men will have much to contribute to medical and surgical science in the future. They have already shown their ability in professional work, and in powers of organising for public health. Those who have had Chinese colleagues in hospital or other work will agree in giving them a high place for efficient work, sweet temper, and resourcefulness. At present, and for some time to come, however, the need would seem to us to be for more medical men and women from this country to go to China. Those who thus fare forth will find ample scope for adventure. They will be facing one of the biggest jobs in the world; and they will have an unparalleled field for enterprise and advance.

ANOMALOUS CASES OF SMALL-POX.

IN our present issue appears an interesting account by Dr. Walter Allingham of three cases of disease which in their early stages resembled chicken-pox, but which subsequently assumed many of the characteristics of small-pox. After the initial symptoms of headache and malaise the patients seem to have suffered but little inconvenience. In each instance a papular rash appeared on the third day of illness and rapidly became vesicular. The distribution of the eruption and the fact that it came out in successive crops was more suggestive of chicken-pox than small-pox. After the initial rash had been out for eight days, a second rash, quite distinct and easily differentiated from the first, made its appearance. It was petechial, deep-seated, and somewhat "shotty" in character, and had a more or less typical small-pox distribution. It may at once be admitted that the diagnosis of cases of illness such as those described by Dr. Allingham is a matter of very great difficulty involving grave anxiety to the medical man in charge of the patients, and to the medical officer of health, who has to give an opinion in such perplexing instances. In the early part of this year Dr. S. M. Copeman, one of the medical officers of the Ministry of Health, read a paper before the Epidemiological Section of the Royal Society of Medicine on an outbreak of varioloid disease of anomalous character which occurred in a limited area of Norfolk and Suffolk and had been investigated by him on behalf of the Ministry. He expressed the view that the disease in question bore a close relationship with the form of small-pox termed "alastrim," and invited discussion on the subject. The cases now described by Dr. Allingham appear to have resembled in certain respects those commented on by Dr. Copeman, and may possibly have been of a similar nature.

Considerable attention has been directed to the study of varioloid diseases in different parts of the world and outbreaks of a malady resembling small-pox, but differing from it in certain important particulars, have been investigated in Jamaica, Trinidad, South Africa, and Brazil. A number of different synonyms have been applied to this disease, such as "varioloid varicella," "amaas," "Kaffir milk-pox," "pseudo small-pox," "alastrim," &c. The question has been debated as to whether this disease, which appears to have occurred in many different parts of the world, is more closely allied to small-pox or chicken-pox, or is a new disease half-way between the two. It is claimed that alastrim, to use one of its many synonyms, differs from varicella in the following respects—namely, the vesicles become confluent in certain cases; the disease attacks adults more frequently than children; and at least partial protection against it is afforded by vaccination. The following characteristics serve to differentiate it from small-pox: The low mortality, which seldom exceeds 2 per cent.; the fact that it is less severe in children than in adults; the rash appears in successive crops, and is generally superficial in character, while the vesicles, which are of a dull whitish colour, are of different shapes and are not unbilicated; absence of secondary fever—after the initial symptoms the patients generally feel perfectly well—and absence of the characteristic smell of small-pox; the limited duration of immunity to alastrim conferred by vaccination and the fact that it is possible to successfully vaccinate the patient shortly after an attack of the disease. Most observers seem to regard the disease as an aberrant form of small-pox.

On the evidence before us we are not prepared to hazard an opinion as to whether or not the anomalous cases of varioloid disease recently met with in England were or were not alastrim. But we call attention to the fact that a disease which appears to differ in essential particulars from the ordinary small-pox met with in this country has come under observation in different districts, in the hope that, should like cases occur in future, the details may be carefully noted and recorded with a view to arriving at definite conclusions. Many departures from the normal are met with in cases of true small-pox which have been modified as a result of antecedent vaccination, and we know how difficult it is at times to differentiate such cases from chicken-pox. But if alastrim is to be accepted as a distinct clinical entity, and if it can be proved to have attacked persons resident in this country, the sooner the fact is recognised the better. In the meantime it will be well to treat all doubtful cases as small-pox, adopting the necessary measures to prevent the spread of the disease.

TREATMENT BY RADIUM.

THE report by Mr. A. E. Hayward Pinch, F.R.C.S., of the work carried out at the Radium Institute, London, during the year 1919 is much more than a record of successful achievement; it is a guide in brief to the present position of the treatment of disease by means of radio-active matter. A large part of the report is given up to the relative merits of the various forms of apparatus which have been tried, to the details of technique desirable in order to use efficiently and economically the costly materials, and to the means of protecting those who constantly work with radium from any harmful and even fatal effects. The fields in which so far radium has been most successful are indicated by the summary on the first page of the report. Out of a total of 822 cases seen for the first time during the year 22 were cured, 101 apparently cured, and 328 improved. Relief, more or less complete, was thus obtained in more than half the number of those who presented themselves. Of the 22 cures 20 come under the heading of "moles, warts, and papillomata," the remaining two being chronic ulceration and keloid. It might be more generally known that short exposures of one to one and a half hours' duration with full-strength applicators are sufficient to cause an almost reactionless exfoliation in from three to four weeks' time in nearly all cases of simple papillomata. Radium is also generally to be preferred to surgical interference in cases of keloid and vicious cicatrix. The results obtained in the treatment of cavernous nævi in infants also leave little to be desired. Mr. Pinch prudently records no cure in the case of more serious tumours, but he admits to 80 apparent cures in rodent ulcer, three in sarcoma, two each in mammary carcinoma, granuloma, and uterine fibroid, and one each in squamous-celled carcinoma of the buccal mucous membrane and of the conjunctiva and in an endothelioma. With the exception of rodent ulcer no operable cases of malignant disease are treated at the Institute, save in the few instances where operation has been positively refused; hence these results are the more remarkable. We understand that several cases have now remained well over a period of 7 or 8 years. Radium has also given excellent results in certain cases of lupus of the skin which had shown themselves refractory to Finsen light. A further useful field for radium treatment has been found in early stages of exophthalmic goitre, and as a preliminary to splenectomy in patients suffering from splenic leucocythæmia. A separate report by Mr. W. L. S. Alton, F.I.C., director of the chemico-physical laboratory, gives some idea of the labour involved in preparing the 771 tubes and applicators during the year, corresponding to an activity of 66 g. of radium bromide. Five thousand bottles of radio-active water were distributed during the same time. The research department under Dr. J. C. Mottram was only opened in May last, but two important investigations have already been communicated to the Royal Society of Medicine, one showing the leucopenia liable to develop in those long exposed to radium emanation, and the other dealing with the curious observation that certain areas of skin do not light up under ultra-violet radiation, a fact which may lead to the radiologist obtaining a clue to the susceptibility of his patient. The report should be studied as a whole by all who wish to keep in touch with the modern development of physical remedies, and will be sent on request, post free, by the secretary of the Radium Institute, 16 Riding House-street, London, W. 1.

In his report on the work of the Manchester and District Radium Institute for the same year Dr. Arthur Burrows deals in some detail with the treatment of carcinoma of the tongue, floor of the mouth, soft and hard palate, tonsils and pharynx, deploring the cursory attention which the radium treatment of these growths has received hitherto and the discouraging results obtained. Dr. Burrows has recently followed the technique devised by Dr. Viol, of New York, which consists in burying within the substance of a tumour unscreened glass emanation tubes, no effort being made to recover these tubes after their insertion. He has applied this treatment to carcinoma of the tongue and mouth. Complete disappearance of the primary growth was obtained in one or two cases, and in others the lesion was replaced by a painless indurated thickening. In some of these cases there is no record of palpable glands, a fact indicating either a very early stage of disease or a lesion of low malignity and feeble infective character. There is, as is well known, a papillated form of epithelioma of the mouth and fauces, accompanied by but little submucous invasion, and this of all forms of mouth cancer is the one which gives the most favourable results to surgical interference or radium irradiation. It cannot, however, be denied that the American technique represents a step forward in the practical application of radium therapy to carcinoma of the mouth. If to this treatment were added early and complete removal by dissection of the glands on both sides of the neck, prognosis in these cases might become much less gloomy than it now is.

EYE-GATE AND EAR-GATE.

IN his entertaining oration before the Medical Society of London, published in THE LANCET of May 15th, Sir D'Arcy Power quotes the Rev. John Ward as remarking of his contemporaries:—

> "There are seueral sorts of physicians 1st. some yt canne talke but doe nothing; 2ly some yt canne doe but not talke; 3rdly some yt canne both doe and talk; 4thly some yt canne neither doe nor talk and these get most money."

The gibe contained in the last five words is charitably regarded by Sir D'Arcy Power as a jest on Ward's part, and is not the aspect of his remarks to which we wish to draw attention here. But Ward was acute enough to base what he thus rounded off with a well-timed gibe on a close observation of human faculties to which those concerned with medical education may give heed. In his preface to the latest continental text-book on surgery[1] Professor Carl Garrè, of Bonn, divides the students who attend his clinic for teaching into two groups which require quite different handling by the teacher. The first and smaller group quickly recognises what is morbid, gets a secure mental grasp of the deviations from the normal, and readily draws analogies; its difficulties begin where theoretical knowledge and critical deduction are needed. The second and larger group, drawn largely from city high schools and seminaries, unpractised in seeing and handling, finds it no easy task to recognise the variations from normal health. Theoretical knowledge is its métier. The two types are well known to modern psychology. The visual gifted thinks in actual pictures of objects and processes; its world of conceptions is alive with form, colour, and movement. The acoustic-gifted thinks in sound and verbal images, translating into this form the written and printed word. The student in whom the former faculty preponderates assimilates with ease the practical side of surgery with all its technique, but finds himself at a loss to systematise his knowledge. His fellow-student may classify and generalise, while the objects of his conceptions remain colourless and ill-defined. Surgical teaching must clearly recognise these differences and the methods of Garrè and Borchard's text-book are consciously based upon an appreciation of them. The two mental outfits are not fixed and unalterable; it is the aim of an intelligent system of teaching to supplement the defects of either. Ability to observe correctly, appreciation of the scientific meaning of what occurs, the logic of physiological and pathological laws—in this sequence, the student will, little by little, form a complete picture of his subject. Garrè quotes with approval Ach's maxim that practical medicine is in large part not merely applied medical science but also applied psychology. The same remark was made in other words by wise and witty Russell Reynolds in an opening address at University

---

[1] Lehrbuch der Chirurgie. Garrè and Borchard. 1920. Leipzig F. C. W. Vogel.

College in the year 1863. His apt characterisation of such types of medical student as David Superficialis Hurry and Cyrus Vane Velox attracted much attention at the time, and may be studied in the reprint of his address in our first issue of 1895. Of equal importance with the knowledge of physical science Reynolds held an "acquaintance with the nature and order of those processes of mind which the child or the savage may apply with instinctive correctness, but which the man of science will use but ineffectively unless he has arranged and analysed them." Subconsciously, doubtless, these principles are in the minds of all our own surgical teachers, whose results are a full justification of their methods. We do not recollect to have seen them stated so clearly as in Garrè's introductory essay, which may have more than a passing interest for the directors of our new surgical units, on whom rests the heavy burden of training the surgeons of the future.

THE RAVAGES OF MEASLES.

Dr. Doig McCrindle's latest annual report as medical officer of health for the county borough of Northampton is exceptional in that it deals with a period of four years, 1915 to 1918, instead of with the latter year alone. This is a procedure which, while it is not practicable in normal circumstances, might be expected to give a more balanced picture than that of the ordinary annual conspectus made from a narrower angle of vision. The report in question does not become thereby so markedly differentiated as might a priori have been anticipated, but this is obviously not an altogether fair test; the slowing of all public health activities, beyond the most essential, during the years of war must have masked a large part of the effect of a report such as the one here under consideration. In respect of measles, however, the advantage of the longer view is sufficiently marked. The report contains a full account of two separate grave epidemics, one occurring in the early part of 1915, the other in the latter half of 1917. Both epidemics were large ones, between 2000 and 3000 cases being notified in each outbreak in a population of 90,000. Both created records, the second being the most extensive ever recorded in Northampton, and the first having a fatality such that over three times as many deaths from measles were registered than in any year since 1898. The death-rate from measles in 1915 actually reached the figure 1·55 per 1000 of population. Dr. McCrindle draws attention to the significant fact that beyond the deaths frankly due to measles 88 deaths occurred in the first six months of 1915 among children under 5 years of age from bronchitis, pneumonia, and broncho-pneumonia; and that the deaths from these conditions diminished as the measles epidemic subsided. It seems very probable that a considerable number of the deaths in young children certified as due to respiratory diseases were in fact due to measles. It is, perhaps, not sufficiently recognised that the measles epidemic is not all above the surface, but that an unknown and probably considerable mass of infection is submerged, and none the less deadly in its effect from having been thus ignored or missed. Northampton is far from being alone in its experience of a severe type of measles during the years of war. Leeds, for example—to quote from an annual report taken at random from other 1918 reports—experienced a serious outbreak in that year. During 1918 over 400 deaths from measles were registered, and the epidemic was the most fatal ever recorded in the city. Over 6 per cent. of the cases died, while of the children under 2 years of age nearly one-fifth of those who developed the disease succumbed. The mortality after the age of 4 was comparatively light, indicating the practical importance of parents guarding their children from risk of contracting the disease during earliest childhood. It is a wholesome antidote to complacency to be reminded from time to time of the long, long trail before us before we can be sure of mastery over this scourge of childhood.

CEREBRAL SOFTENING SIMULATING LETHARGIC ENCEPHALITIS.

IN his exhaustive article (see p. 1152) on lethargic encephalitis, based upon two clinical lectures delivered at the University of Edinburgh, Dr. Edwin Bramwell deals with the protean symptomatology of the disease which may, at the outset, suggest cerebral hæmorrhage or embolism or, at the other extreme, functional disease with emotional disturbance. It is not yet sufficiently recognised that all the symptoms of lethargic encephalitis may be due to other cerebral diseases. At a recent meeting of the Société Médicale des Hôpitaux of Paris, MM. E. Baudoin and P. Lantuéjoul reported a case in which cerebral softening simulated lethargic encephalitis.

A woman, aged 57 years, was attacked on Feb. 3rd, 1920, with slight headache, and on the 4th vomited. On the 5th, when she came under observation, she responded well to questions, and said that the headache was less. Examination revealed only old hemiplegia and slight convergent strabismus of the left eye. On the 6th she was in a state of somnolence, which increased on the 7th, when she was admitted into hospital, with a temperature of 101·8°F. On the 8th she lay in a somnolent condition on her back. She answered questions correctly but with difficulty, and without raising her eyelids. It was necessary to repeat the question in a loud voice, and even to shake her in order to obtain an answer. She declared that she did not suffer and no longer had headache. The temperature was 100·7°, the pulse 76, unequal and irregular. The respiration was 20 and regular. She could not completely raise her eyelids, and they had to be forced apart in order to examine the pupils. These were unequal, the left being the smaller and not reacting to light; the right was irregular and reacted feebly. The eyeballs could be directed only to the right. There was slight rigidity of the neck, but Kernig's sign was absent. Lumbar puncture yielded clear fluid under normal tension containing 256 leucocytes to the cubic millimetre. The clot of centrifugalisation was composed almost entirely of intact polynuclears, with a few lymphocytes and red corpuscles and without microbes to direct examination. Culture-tubes of gelose and ascitic fluid remained sterile after inoculation. As there was incontinence of urine the patient was catheterised every six hours, and 750 g. of slightly albuminous urine were obtained. Death occurred on Feb. 10th. At the necropsy no meningeal lesions were found. The right cerebral hemisphere was the seat of softening, cortical and deep and almost total. The lesion was so extensive and marked that it was impossible to distinguish old from recent softening. Thus softening which came on insidiously produced the triad of symptoms of lethargic encephalitis—persistent somnolence, ocular troubles, and fever. However, the abundance of the leucocytosis and the polynucleosis of the cerebro-spinal fluid threw doubt on this diagnosis.

Babinski and other French writers have called attention to this leucocytosis as symptomatic of extensive cerebral softening. In one case the hyperalbuminous cerebro-spinal fluid contained 40 leucocytes to the cubic millimetre, with marked polynucleosis, and in another 450 leucocytes almost entirely intact polynuclears. These leucocyte reactions are abundant in the early days of the lesion, and consist at first of intact polynuclears, then of lymphocytes. They may disappear rapidly.

ANTISCORBUTIC ORANGE-JUICE POWDER.

WE have more than once pointed out how convenient it would be if the vegetable and fruit juices containing antiscorbutic substances could be reduced to a powdered form without impairing their activity. In our issue of May 22nd Surgeon-Captain P. W. Bassett-Smith described an investigation, recently carried out at Greenwich, into the antiscorbutic potency of lozenges made from lemon-juice concentrated in vacuo without heat. In guinea-pig experiments their potency was very high. According to a paper on "The Antiscorbutic Properties of Concentrated Fruit Juices," by Arthur Harden and Robert Robison, published in the April number of the *Biochemical Journal*, the drying of fruit-juice has been successfully carried still further. The technical procedure has followed the lines of milk-powder production by the spray process, which avoids a temperature likely to reduce, if not to kill, the potency of the antiscorbutic agent. From the results obtained it is reported that a highly active dried orange-juice can readily be prepared on a commercial scale which will keep after prolonged storage under suitable conditions. The orange-juice, mixed with corn syrup, was forced as a fine spray into a chamber where it met a current of air heated to 75°–80°C. The drying was almost instantaneous, and the product when tested on guinea-pigs was found to afford complete protection from scurvy. As the authors point out, the peculiar value of such a substance lies in its adaptability for infant feeding and for the use of expeditions of long duration, where fresh fruit and vegetables are unobtainable and when transport must be reduced to a minimum. It would appear that orange-juice is decidedly superior to vegetable juices in regard to keeping its activity when exposed to relatively high temperatures. In spite of this observation the investigation of the effects of storage on dried orange-juice at tropical temperatures remains to be determined. We have already drawn attention to the fact that in the preparation on the large scale of citric acid from lemon-juice by separating the acid in the form of precipitated calcium citrate the antiscorbutic material escapes unimpaired in the filtrate. Surely, it is worth while to deal with this filtrate by the method suggested herein, and so to conserve a valuable accessory food factor.

VENEROID ULCER.

Dr. George Manghill Olson,[1] assistant professor of dermatology and syphilis at the University of Minnesota Medical School, gives this name to a condition first described by Welander in 1903 and occurring in the form of ulcers about the vulva of girls or women who had not been exposed to venereal disease. Constitutional disturbance is absent, and the first symptom noted by the patient is the presence about the vulva of one or more *sores with a slight sticky discharge. The ulcers* are round or oval, with their edges raised, sharply defined, and not undermined. There are no signs of inflammation in the adjacent tissues. The lesions are rather painful and bleed readily when touched or scraped with a dull instrument. There is no discharge of serum as in the primary lesion of syphilis, and the inguinal glands, as a rule, are not enlarged. Healing takes place under indifferent treatment in about a month, leaving typical superficial round or oval scars with slightly raised edges. In spite of these differences the ulcers may resemble in their general appearance hard chancre, chancroid and moist papules of syphilis. Microscopical examination of the discharge shows a great variety of bacilli and cocci, but the causal organism has still to be discovered. The Gram-positive bacillus described by Lipschutz is probably only a saprophyte. Unlike chancroid the disease is not auto-inoculable, and no cases have been reported in which the husband has been infected. The diagnosis is made by the history of non-exposure to venereal infection which may be corroborated by the presence of a hymen, an acute onset, absence of constitutional symptoms, a characteristic depressed round or oval ulcer with no induration, and the absence of the *Spirochæta pallida*, Ducrey's bacillus, the diphtheria bacillus, and the spirochæte and fusiform bacillus of erosive vulvitis.[2]

THE POST-GRADUATE MOVEMENT IN NEW YORK.

SUPPORTERS of the post-graduate movement in Great Britain will envy the results of a campaign which has been opened in New York for the establishment and furtherance of post-graduate medical education. An Endowment Fund, started in August last, has already realised more than £100,000, and New York is already talking of a legitimate ambition "to become the medical centre of the world." It would seem that from 3000 to 5000 American physicians went abroad in the years before the war, and those responsible for the new association consider that proper provision in New York for the needs of these men will save both time and money. Honourable rivalry spurs contesting parties onwards, and the view of our Fellowship of Medicine is that London should become just such a centre as New York is now contemplating. And this view is shared by many patriotic Americans, who see that London, by geography as well as by its metropolitan position in a scattered empire, has the greater opportunity of becoming representative of world needs. But the London movement, inaugurated in a poorer country, has not yet attracted the pecuniary support which New York can claim already. Few British rich men—and we are not without them—have yet come forward to assist post-graduate medical education in this country. The Fellowship of Medicine will welcome their interest, and it seems to us that a British Endowment Fund might captivate the imagination of the wealthy. Work, more far reaching in its scope and possibilities than is generally recognised, is being carried forward by the Fellowship with quite insufficient financial support. Post-graduates are arriving in London week by week from quarters which have not previously looked upon England as a centre for medical post-graduate work. During the last few days medical graduates from Toronto, Vancouver, *Adelaide, Melbourne, Ottawa,* Madras, the Transvaal, Bagota, and Christiania have presented themselves at the offices of the Fellowship, whilst postal inquiries, we are informed, come in daily. Suggestions are to hand from France for the linking up of post-graduate work in Paris with that in London for the mutual benefit of French and British practitioners, while the movement is receiving firm American support. There is no reason to suppose that the patriotic desire of the American graduate to make New York the medical centre of the world will stop the supply of American graduates.

THE NEW RENT BILL.

THE new Rent Restriction Bill, presented to Parliament by Dr. Addison on May 20th, will have considerable practical interest for many of our readers. The text of the Bill has now been issued, and seems, on the whole, to have met with a favourable reception, except that some dissatisfaction has been expressed that no provision has been made to meet the case of premises used wholly for business purposes. Until recently the great majority of medical men resided and practised at the same address, and this aspect of the problem will affect as yet but few. The terms of the Bill amount to a revision of the Rent Restriction Act of 1915, and provide for an extension of the Amending Act of last year for a period of three years from the time the Bill becomes authorised. The general impression is that the Bill will speedily become law, and therefore its provisions claim careful study in the directions which will affect both landlord and tenant alike. Generally speaking, the broadening of the scope of the Act will be welcomed, since its provisions are to be extended to houses which in 1914 commanded a rental of £105 in the London district, of £90 in Scotland, and of £78 in England and Wales, whereas in the Act of 1919 the rentals provided for were respectively limited to £70, £60, and £52. This extension will obviously give relief to a larger circle of tenants. At the same time the promoters of the Bill have borne in mind the case of the landlord responsible for repairs. The expense of keeping a house in decent repair has vastly increased, and the result is a deplorable set-back in the condition outside and in of tenements. This fact is detrimental, of course, to both tenant and landlord; there is inconvenience, including possibly sanitary defects, to the former, and depreciation to the interests of the latter. The new Bill allows an increase of rental, provided that reasonable repairs be carried out before the permitted increase of rent. Subject to these, amongst other conditions, the landlord may increase the rent by a maximal limit of 40 per cent. To a medical man it is often highly important that he should remain in his familiar house, and the new Rent Restriction Bill, when it becomes an Act, will help him materially in this direction.

DURING his forthcoming visit to Wales the King will open the North Wales Sanatorium at Llangwyfan, near Denbigh, on July 16th, and the South Wales Sanatorium at Talgarth, Breconshire, on July 17th. Both these sanatoriums have been constructed to meet the needs of the King Edward VII. Welsh National (Tuberculosis) Memorial Association.

ROYAL PORTSMOUTH HOSPITAL.—In accordance with the recommendation of a subcommittee appointed to consider the question, the management committee has decided to retain the ticket system of admission to this hospital. The suggested alteration in the value of the tickets—that is, the issue of two instead of four for every sovereign subscribed—is still under consideration.

THE FUTURE PROVISION OF MEDICAL AND ALLIED SERVICES.[1]

AN INTERIM REPORT OF THE CONSULTATIVE COUNCIL FOR ENGLAND.

A BRIEF preface by Dr. Addison, the Minister of Health, introduces the Report of the Consultative Council of Medical and Allied Services upon the provision that should be made in the future for developing these services for the greatest public good.

Prefatory Note by the Minister of Health.

"This Report, the first to be received from the Consultative Council on Medical and Allied Services established under the Ministry of Health Act, 1919, is published in order to facilitate discussion of the questions raised in it. Action is being taken by the Ministry of Health and the local authorities in relation to a number of matters touched upon in the Report; and proposals for action in other directions are in process of formulation. Many of the Council's recommendations must necessarily be considered in relation to a comprehensive policy for the extension and development of health services (including the question of the future administration of services at present entrusted to Poor-law authorities), which will be submitted to Parliament by the Government in due course."

Terms of Reference to the Council.

In October last the following reference was made to the Consultative Council on Medical and Allied Services:—

> To consider and make recommendations as to the scheme or schemes requisite for the systematised provision of such forms of medical and allied services as should, in the opinion of the Council, be available for the inhabitants of a given area.

This document is the response of the Consultative Council who, finding that to give a detailed report on so large a reference would occupy longer time than was at its disposal, and having regard to the need for promptitude in the construction of a national health policy, has returned an Interim Report setting forth the direction of its deliberations and conclusions.

The Scope of the Interim Report.

The first section of the Report prepares us for a complete pattern of organisation designed in scope, availability, and distribution to meet the needs of the community of to day. The growing cost of medical services is noted, as well as the recognised union of preventive and curative medicine, and the increasing need of institutional treatment side by side with an increasing popularity of such treatment.

To provide for these things the scheme considers medical services as classified into: (1) those which are domiciliary as distinct from those which are institutional; and (2) those which are individual as distinct from those which are "communual," meaning those which concern a section of the population and not a sick subject. The words of the Report require no explanation:—

> 9 We begin with the home, and the services, preventive and curative, which revolve round it—viz., those of the doctor, dentist, pharmacist, nurse, midwife, and health visitor. These we style domiciliary services, and they constitute the periphery of the scheme, the remainder of which is mainly institutional in character. A Health Centre is an institution wherein are brought together various medical services, preventive and curative, so as to form one organisation. Health Centres may be either Primary or Secondary, the former denoting a more simple, and the latter a more specialised service.
>
> 10 The domiciliary services of a given district would be based on a *Primary Health Centre*—an institution equipped for services of curative and preventive medicine to be conducted by the general practitioners of that district, in conjunction with an efficient nursing service and with the aid of visiting consultants and specialists. Primary Health Centres would vary in their size and complexity according to local needs, and as to their situation in town or country, but they would for the most part be staffed by the general practitioners of their district, the patients retaining the services of their own doctors.

---

[1] Ministry of Health: Interim Report on the Future Provision of Medical and Allied Services. London: His Majesty's Stationery Office. 1920.

11. A group of Primary Health Centres should in turn be based on a *Secondary Health Centre.* Here cases of difficulty, or cases requiring special treatment, would be referred from Primary Centres, whether the latter were situated in the town itself or in the country round. The equipment of the Secondary Centres would be more extensive, and the medical personnel more specialised. Patients entering a Secondary Health Centre would pass from the hands of their own doctors under the care of the medical staff of that Centre. Whereas a Primary Health Centre would be mainly staffed by general practitioners, a Secondary Health Centre would be mainly staffed by consultants and specialists. It would be a consultant service in function and would be carried out by specialists or by general practitioners acting in a consulting capacity.

12. Secondary Health Centres must of necessity be situated in towns, where alone an efficient consultant service and adequate equipment could be expected, and the necessary means of communication exist. The selection of these towns will need careful consideration, and full information will be required as to the extent of existing provision of hospital and allied facilities, and of its distribution in relation to population and means of public conveyance. In rural areas the natural currents of traffic and business and existing medical facilities will usually indicate the town or towns in which a Secondary Health Centre may best be placed. In this connexion we would like to point out the importance of carrying out a "Hospital Survey" at an early date. The results of this survey would afford data for recognising the areas in which the existing provision is inadequate, and the degree of the inadequacy. The Secondary Health Centres would vary in size and elaboration according to circumstances.

13. Secondary Health Centres should in turn be brought into relation with a *Teaching Hospital* having a Medical School. This is desirable, first in the interest of the individual patient, that in difficult cases he may have the advantages of the highest skill available, and secondly in the interest of the medical men attached to the Primary and Secondary Centres, that they may have the opportunity to follow the later stages of an illness in which they have been concerned at the beginning, to make themselves acquainted with the treatment adopted, and to appreciate the needs of a patient after his return to his home. In those towns where teaching hospitals exist, Secondary Health Centres would sometimes be merged in them.

The accompanying illustration shows the scheme of services for a county area, in a diagrammatic way, and Gloucestershire, under the guidance of Dr. J. Middleton Martin, has already laid down some such pattern, which is also reproduced in the Report.

This section closes with the declaration that the dominant purpose underlying the recommendations is to secure provision of buildings and equipment, services suitably correlated and available for all, opportunity for the best work and furtherance of knowledge, coördination of preventive and curative medicine, and freedom of action for doctor and patient.

Domiciliary Service.

The second section deals with Domiciliary Service, defined as the first element in any scheme of systematised medical services, comprising the doctor, dentist, pharmacist, nurse, midwife, and health visitor. The Report runs:—

19. *Doctors.*—A doctor should be so located as to be reasonably accessible to his patients. He would attend his patients either at their homes or his surgery, and would carry out such treatment as falls within his competence; or, if in his judgment, a patient could be more advantageously treated in the Primary Health Centre, he would be able to arrange for the patient to be transferred there under his care. He would attend in childbirth in their own homes such patients as arranged with him, or, if desirable, would secure their transference to a maternity bed in a Primary Health Centre or special institution.

20. Where the assistance of a consultant or specialist was needed, and it was impossible to transfer the patient to the Primary or Secondary Health Centre, it should be possible for him to summon such assistance to the patient's home.

21. The custom whereby each general practitioner has his consulting-rooms at his own house, should, under ordinary circumstances, continue, but where, as in certain congested areas, it is impossible for a doctor to provide adequate accommodation at his own expense, it should be possible, if the public interest demanded it, for the Health Authority to provide such accommodation at the Primary Health Centre, or elsewhere, on such terms as are reasonable, and after previous consultation with a Local Medical Advisory Council. Where local conditions, and medical opinion, favoured the plan collective surgeries might with advantage be tried, either attached to a Primary Health Centre, or set up elsewhere.

22. Work in preventive medicine by the general practitioner would be carried out both in the homes of his patients and in the Primary Health Centre, and the Health Authority should be enabled to make specific payments for such work.

23. We think that in any scheme of improved medical services the duty of the general practitioner to advise how to prevent disease and to improve the conditions of life among his patients should be an important element in his work.

24. The general practitioner, if adequately trained, should play a valuable part in the work of the communal services—*e.g.*, antenatal supervision, child welfare, both before and during school age, physical culture, tuberculosis, venereal disease. He will be the first link in any chain of services to improve the conditions of industry, and to prevent any unfavourable or injurious influence upon the health of the workers.

The section further takes note of the needs of a regular pharmacy service in connexion with medical treatment at the periphery, and similarly of properly organised domiciliary nursing and midwifery.

Primary Health Centres.

The third section deals with Primary Health Centres in detail.

In the Primary Health Centres the health services and allied activities are gathered together and administered by the general practitioners of each district, the work being coördinated and supplemented by the Secondary Health Centre for the area. The Primary Health Centre has as its nucleus a district hospital, of which there are three types according to the population served. The accommodation of the projected building and its purposes are thus described, the descriptions being elucidated by plans and elevations drawn to scale.

37. *Accommodation.*—There would be wards of varying sizes, and for varying purposes, including provision for midwifery. The increasing employment of open-air treatment of illness would be provided for. Clinics would be equipped where doctors could see their patients and consult with each other. Further accommodation might include the following:—Operating room, with the necessary equipment; radiography rooms; laboratory for simple investigations; dispensary; baths, including simple hydrotherapy; equipment needed for massage, electricity, physical culture; a public mortuary; a common room which would serve as a meeting-place for the general practitioners of the district, and to store clinical records on an agreed and standardised basis.

It is designed also to aggregate at these centres a dental clinic, all the ancillary services falling under the headings of pre-natal care and child welfare, treatment of school children, physical culture, and early or preventive treatment of tuberculosis and occupational diseases.

Plans for the buildings are included in the Report, but the possibility of adapting existing Poor-law infirmaries and cottage hospitals is recognised, as are the possible inconveniences and ultimate expenses of such adaptations. It is suggested that war memorial hospitals might be constructed on the plans of the Report.

The arrangement for staffing the Centres is elaborate and ingenious. Every general practitioner is to attend his own patients requiring hospital treatment at the centre, irrespective of their status, but the practitioner's private patients will pay the Centre for accommodation and the doctor for his work. Consultant and specialist help will be available from the Secondary Health Centre, a telephone and ambulance service being an integral part of the scheme. At each centre one man will become a director of one of the special services—tuberculosis, venereal, treatment of school children, for example—having specially fitted himself for the post, and these directorships will be part-time posts paid on a time basis. This is a happy way of linking up the Primary and Secondary Centres with each other and with the teaching schools, as the part-time director of special services at the Primary Centre will have received his intensive training at the larger foci.

The section closes by describing the general practitioner's share in the scheme as follows:—

51. *Nature of the General Practitioner Service.*—It will be seen under the scheme so far outlined that the work of the general practitioner would be mainly domiciliary, but partly institutional, mainly individual but partly communal; that at the Primary Health Centre he would treat such of his patients as attended there; that at the Centre there would be provision of all needful equipment; and further, appointment as salaried director of one or more communal services would be open to him. In this way the advantages of organisation, hand-in-hand with the preservation of liberty of thought and action, would be secured.

The idea of a whole-time salaried service for all doctors was considered and rejected.

Secondary Health Centres.

The fourth section deals with Secondary Health Centres, and brings us to grips with the voluntary system for the support of hospitals, which is specially dealt with in the next section. The Secondary Health Centres are to be arranged in the large towns and the work will be mainly of a consultative type. The nucleus here is the existing general or county hospital, though additions and adaptations are contemplated. They will

receive the cases referred to them from the Primary Centres, serve as models for these, and have the following equipment:—

57. Such equipment would include:—General Services: Medical, Surgical. Special Services: Obstetric, Gynæcological, Ophthalmological, Throat and Ear, Dermatological, Orthopædic, Genito-urinary, Dental, and Industrial Hygiene. Laboratories: Pathology in all its branches. Other Services: Pharmacy, Radiology, Electrotherapy, Hydrotherapy, Radiant Heat, Physical Culture, Massage, Nursing. In existing circumstances some of these services might have to be in separated, though closely coördinated, institutions.

The Report continues:—

59. The Curative Services of Secondary Health Centres would have as their nucleus existing hospitals, for to and from these latter flow the currents of medical work, and they are part of the life of their districts. In the comprehensive organisation contemplated, the functions of existing hospitals would be considerably extended, and the present buildings would not be large enough for such purposes, and would need to be either supplemented or enlarged. In those areas in which there are modern and well-equipped Poor-law infirmaries the necessary accommodation might be partly provided by the transfer of these institutions from the guardians to the Health Authority. We strongly urge that this reform should be carried out at the earliest possible moment. If this were accomplished not only would much of the increased accommodation required be provided, but a better classification of cases would be possible. The infirmary buildings could accommodate the large number of routine cases of illness which, though neither difficult nor dangerous, is disabling and as such needs to be promptly cured so that breadwinners and mothers of families may be restored to their work. At the present time, with pressure on the beds in the hospitals, these, from an economic point of view, important cases, are necessarily postponed on account of the claims of graver and more urgent illnesses.

60. It would, however, be necessary in many areas to establish complete and model Secondary Health Centres provided with every modern requirement. The separation of the buildings which constitute a Secondary Health Centre, though sometimes in actual circumstances necessary, is a real disadvantage on grounds of both efficiency and economy, and should be regarded as a temporary expedient to be supplanted, so soon as practicable, by adequately equipped buildings grouped on the same site, thus securing collaboration and unity of control.

The personnel of the consultant services would, it is suggested, be the staffs of the hospitals, though reluctance is anticipated from some of the members. For it is suggested that consultants would be part-time paid officers, with extra fees for special work, and with scheduled duties. Eligibility to serve as consultant or specialist is to be evidenced by any or all of the following points: Special study, tenure of appointment affording special opportunities, and local professional recognition. With reference to the last, the Report says: "We contemplate that general practitioners should be eligible for these posts, and we should regard their representation in the consultant services and on the staffs of the Secondary Health Centres as an advantage."

Private or paying wards in Secondary Health Centres are to be provided, thus meeting a known need.

72. We recommend that standard charges should be made in the public wards and for other curative services, though it is possible this standard charge might vary in different parts of the country. We contemplate that such charges would more often be met by some method of insurance, though private patients recommended by their doctors would have the right to avail themselves of these services by direct payment.

73. The standard charge at the Primary and Secondary Health Centres would include residence, food, nursing, and all equipment; at the Secondary Health Centre provision would also need to be made for the payment of consultant services. It would be open to any patient to request the advice of a consultant or specialist of his own selection, the patient being responsible for the fee.

The Teaching Hospital and the Voluntary Hospital System.

The Report considers, in the fifth section, all the supplementary services and the position of teaching hospitals with medical schools. The following are the far-reaching proposals concerning the Teaching Hospitals:—

76. The Teaching Hospital would receive cases of unusual difficulty, and those requiring specialised knowledge or equipment, and in so far as is necessary, patients suitable for either primary or secondary hospitals should be freely admitted to Teaching Hospitals.

77. Similarly, the laboratories and special departments of this Teaching Hospital would be a court of reference and would inspire and lead the laboratory services of the Health Centres attached to them.

It is intended that the hospital should be the centre of post-graduate instruction, and initiate and guide collective investigation in which the staffs of the Health Centres would play their part.

The pecuniary position and needs of the voluntary hospitals are then summarised, the Report describing them thus as an essential part of the scheme:—

83. Some hospitals, which on account of their endowments have not hitherto appealed to the public, are now beginning to do so, their endowments being insufficient to meet the increased expenditure. Their entry into the field has made it still more difficult for those who have hitherto depended entirely on subscriptions.

84. We hope that the scheme we have suggested will help these institutions, since these institutions are an essential part of the scheme. They should receive grants in aid for work carried out, and we hope that those of them which are suitably equipped may receive grants in aid for carrying on research, and that those with schools attached may also be assisted in their most important work of medical education.

85. We take this opportunity of expressing our admiration of the way in which the voluntary hospitals have carried out their magnificent work, in spite of innumerable difficulties and through long years, when less interest was taken than now in the health of the poor, or in the painstaking research which has for its purpose the prevention of disease.

86. If no hospital exists in a given area it would have to be provided. If a voluntary hospital does exist its assistance would be welcomed, both in the provision of beds and equipment, and in the accumulated experience of its medical staff and management, which would be valuable to any Health Authority. The benefits they would receive under the scheme would be in proportion to the extent of their coöperation and their readiness to come into coördination with the general plan.

The Report here sets out the reasons for the existing difficulties in hospital finance, while the greatest admiration for the voluntary system is expressed, and the resolution to use the voluntary hospitals wherever available in the general scheme is registered. The need for standardised clinical records is pointed out.

Administration in Relation to the Doctor.

Under the sub-head of Administration, also in the fifth section, the need for a new type of health authority to bring about unity of local control for all health services, curative and preventive, is laid down thus:—

94. As regards the nature of this new Health Authority, there are some who favour a Statutory Committee of an existing Local Authority, whereas there are others who favour the establishment of an *ad hoc* independent body for the purpose of administering health services alone. The question which of these courses is preferable is one upon which we would rather defer any final expression of opinion.

95. Whatever may be the nature of the future Health Authority, it will be necessary to devise machinery for securing the complete intercommunication and coördination above referred to, and what we desire to emphasise here is that such intercommunication is vital to an efficient health organisation.

96. *Relation of the Medical Profession to Administration.*—In the opinion of the Council, one of the conditions of efficient service is that the medical profession as such should come into organic relation with health administration. The success of the service will depend upon the coöperation and the enthusiasm of the medical profession, and if doctors play a responsible part in the administration, the Health Authority will have the advantage of their knowledge, and the local profession will feel its reputation and interests identified with those of the service.

97. To carry this idea into effect, we recommend: (1) that the medical profession be represented as such in the future Health Authority; and (2) that a Local Medical Advisory Council be associated with each Health Authority.

98. *The Composition of the Health Authority.*—The representatives elected by popular vote should hold a majority on the Health Authority. We suggest that they should constitute three-fifths of the membership, and that the remaining two-fifths be made up of persons whose special knowledge would be of value in health questions, a majority of whom should be medical representatives nominated by the Local Medical Advisory Council. By such an arrangement, the elected representatives would hold the majority of votes, and the nominated members would contribute to the skilled knowledge necessary for successful deliberation. Methods should be provided whereby the Health Authority could obtain the advice and ascertain the collective opinions of those engaged in allied services, such as pharmacists, nurses, or midwives.

99. *Local Medical Advisory Council.*—In any areas in which there is established a Health Authority, we advise the setting up of a Local Medical Advisory Council, consisting of, say, 10 to 20 members, the number varying according to the needs of the area. This Council should be elected periodically by and from all the registered practitioners resident in the area by means of the postal vote or otherwise, and the Health Authority might be made responsible for conducting the election. The Principal Medical Officer and the two Chief Assistant Medical Officers (as defined below) should be ex-officio members of this Advisory Council.

The administrative head of the medical service of the area will be the Principal Medical Officer of the area, with two Chief Assistants, his staff being composed of a varying number of assistant medical officers and of the heads of the various special and ancillary services in the area. The local Medical Advisory Council is to have power to appoint committees for special purposes.

Details of Certain Forms of Provision

In the sixth section follows the provision to be made under the headings of a systematised scheme for (*a*) Laboratory Services; (*b*) Dental Services; (*c*) Maternity and Child Welfare Services; (*d*) Physical Culture; and (*e*) Recuperative Centres. The Laboratory Services at the primary centres will give facilities to the general practitioner, while the staffing will be in the hands of the director of the laboratory at the secondary centre, with which it will be in communication by telephone. It is further suggested that the laboratories, both at the primary and the secondary centres, should be linked up with a special laboratory at each University centre.

The Report closes with a full recognition of the value of physical culture and remedial physical treatment and of recuperative centres, to be used either for restorative or preventive purposes.

Summary of Recommendations.

In the seventh section there is given a summary of the effect of the various recommendations as to the elements which should, in the view of the Council, be included in schemes for the systematised provision of medical and allied services for the inhabitants of a given area. The summary is to be understood, not as governing or placing an interpretation upon the fuller paragraphs of the Report, but only as drawing attention in a conveniently brief form to the main conclusions. It is recommended that schemes should include provision for the following services and personnel:—

Services and Personnel.

A.—*Domiciliary* (pars. 18 to 35) (including both curative and preventive work). Personnel: Doctors, pharmacists, nurses, midwives, health visitors and other officers of the health authority.

B.—*Primary Health Centres* (pars. 36 to 52), including medical, surgical, and maternity beds; out-patient clinics, dental clinics; accommodation for equipment needed for treatment and investigation, accommodation for the work of communal services, accommodation for workers in ancillary services, ambulance service. Personnel: General practitioners, visiting consultants and specialists, officers engaged in communal services, visiting dental surgeons, workers in ancillary services.

C.—*Secondary Health Centres* (pars. 53 to 73), including facilities for curative services in cases requiring highly specialised diagnosis or treatment, accommodation for the work of communal services, dental clinics, accommodation for workers in ancillary services, ambulance service. Personnel: Consultants and specialists, officers engaged in communal services, dental surgeons, workers in ancillary services.

D.—*Supplementary Services* (para. 74), including provision for facilities for specialised treatment of such conditions as tuberculosis, mental disease, &c. Personnel: Specialists in the appropriate forms of treatment, workers in ancillary services.

E.—*Teaching Hospitals with Medical Schools* (pars. 75 to 80), including facilities for treatment of cases of unusual difficulty, facilities for research, facilities for post-graduate study (including training for communal services). Personnel: Consultant, teaching, and research work, workers in ancillary services.

A closing paragraph repeats the need for the encouragement of research and the operation of a system of standardised clinical records. The chairman of the Council, Lord Dawson of Penn, and the vice-chairman, Colonel C. J. Bond, have been authorised to sign the Report on behalf of the Council.

Consultative Council on Medical and Allied Services.

The following is the list of members of the Council: The Right Hon. Lord Dawson, G.C.V.O., K.C.M.G., C.B., M.D., F.R.C.P. (*Chairman*), C. J. Bond, C.M.G., F.R.C.S. (*Vice-Chairman*), N. G. Bennett, M.B., B.Ch., L.D.S. Eng.; R. A. Bolam, O.B.E., M.D., M.R.C.P.; Victor Bonney, F.R.C.S.; H. G. Dain, M.B., M.R.C.S.; A. Fulton, M.B.; Sir William S. Glyn-Jones, T. A. Goodfellow, C.B.E., M.D., M.R.C.S.; G. E. Haslip, M.D., M.R.C.S.; T. Eustace Hill, O.B.E., M.B., B.Sc.; F. G. Hopkins, D.Sc., F.R.S.; Miss M. H. F. Ivens, M.B., M.S.; Miss Janet E. Lane-Claypon, M.D., D.Sc.; A. Linnell, M.R.C.S.; J. A. Macdonald, LL.D., M.D.; E. W. Morris, C.B.E.; John Robertson, C.M.G., O.B.E., M.D.; T. W. Shore, M.D., M.R.C.S.; Sir William A. Tilden, D.Sc., F.R.S.

THE FIRST REPORT OF THE WELSH CONSULTATIVE COUNCIL.

THE Welsh Consultative Council is a composite body, comprising not only representatives of the Medical Profession, but also of National Insurance, and of Local Health Administration. Under the chairmanship of Sir Edgar Jones, it has with commendable rapidity presented its first Report, which sets forth how systematised provision may be made for improving and maintaining the health of the Principality.

The object is to ensure that sufficient and efficient medical and nursing services of all kinds are available to the community. The plan proposed is to divide the country into medical areas, each with a main medical centre. For instance, in the south Cardiff would form one medical centre and Swansea another. Each area would then be subdivided into districts according to convenience of geographical position and transit facilities. Each district would have an institute, which would act as (1) a general medical and surgical hospital for in- and out-patient work; (2) a centre for maternity and infant welfare, school, tuberculosis, dental, venereal, and other clinics; (3) a medical institute with laboratory, library, record and research department, and facilities for scientific meetings; (4) a centre from which nursing services, health visiting, and home helps would be directed; (5) a base for systematised motor ambulance service; and (6) a centre for public health administration; in addition, out-station clinics would be needed. The clinical work of the institute would be conducted by the medical practitioners of the district (suitably remunerated for their services), who would contribute to the institute and obtain from it regular information as to the health of the district. Unusual and difficult cases would be either transferred to the main medical centre, or a consultant from there would be called up to the institute. Secondary institutes on a smaller scale would be required in certain districts, modified to meet local needs. These would be based on the main institute of the district, just as this in its turn would be based on the medical centre for the area. General hospitals, Poor-law infirmaries, and cottage hospitals already in existence could be utilised and coordinated forthwith. Asylums, fever hospitals, convalescent homes, and the like would be linked up with this scheme of the medical service. The way in which the scheme would apply in three typical areas is set forth in the Report; the Aberdare Valley is taken to represent an industrial and urban district; East Carmarthenshire, including Llanelly and the valley up to Ammanford, represents a combined industrial and rural district; and the County of Merioneth a purely rural district. Due weight is given in the Report to the need for after-care treatment and for holiday homes for the tired whose condition is not yet pathological. Open-air schools are advocated for healthy children as well as for defective; fortunately they have the advantage of being cheap to construct. The need for pit-head baths and washing facilities for factories is emphasised. Standards are suggested as to the personnel required. One qualified dentist is held to be needed for every 4000 population; one doctor for every 400 homes in urban communities or 300 homes in rural; one health visitor per 1000 houses in populous centres, and one per 500 to 750 houses in less populous districts. Clearly this personnel is not available to-day, but the Report supplies a standard to be aimed at. The claims already put forward by Cardiff are that many of the proposals are only what have for some years been in operation in that city, and from Merthyr that very little modification of existing medical services would be needed to bring them into accord with the suggestions in the Report, indicate that the plan put forward is essentially practical. It makes use of all available medical service, coordinates it into a workable organisation, and indicates where addition to the service would be needed.

The Report brings out clearly two points: (*a*) there is an entire lack of organisation in medical service to-day; and (*b*) the personnel and institutions already in existence, if properly organised, would go far to meet the needs of an efficient service. Organisation of personnel and institutions already in existence is not an expensive matter, and this part of the programme could be put into operation forthwith.

SUBSEQUENT to a meeting of the Faculty of Medicine on May 22nd the Vice-Chancellor of the University of Brussels presented the medal of honour of the University to Lord Dawson, Sir Leslie Mackenzie, and Sir William R. Smith in recognition of their services to preventive medicine.

TUBERCULOSIS.

Administrative Control of Tuberculosis.

THE Parliamentary reports already published in THE LANCET concerning Dr. Addison's scheme for the reorganisation of the tuberculosis campaign may be supplemented by the following notes. Speaking in the House of Commons on the National Health Insurance Bill he pointed out that the administration of sanatorium benefit was to be transferred from the insurance committees to local health authorities, the object of the Bill being mainly to provide for an increase in the rate of benefits under the National Health Insurance Act, in view of the fall in the value of money. He argued that this transfer would imply more efficient administration, and that it had become obvious that much of the expenditure hitherto incurred in connexion with sanatorium treatment had been wasted. It was clear, in his opinion, that it was impossible to deal with this matter unless it was undertaken by one authority competent to deal with every aspect of it. He promised, however, that there should be an opportunity for coöpting members of insurance committees, who had special experience of tuberculosis, on the new authority set up. When the clause came up for discussion at the Committee stage, it was evident that the House of Commons agreed with Dr. Addison in regard to the transfer.

Tuberculosis Settlements in Scotland.

In a circular, dated April 30th, the Scottish Board of Health reminds local authorities of the recommendations of the Inter-Departmental Committee's Report of August, 1919, on the treatment of tuberculosis. The object of this reminder is to draw the attention of the Scottish local authorities to the possible establishment of one or more village settlements in Scotland, and to intimate that at an early date a conference for the free discussion of suggestions as to action will be arranged. The Board invites definite views on the subject.

King Edward Memorial Association.

For the first time since the establishment of the King Edward Memorial Association the council of that body met at Carnarvon on April 23rd, under the presidency of Major David Davies, M.P. He announced that at last every county in Wales had joined in the anti-tuberculosis campaign—one of the few national campaigns in Wales. Referring to grants made to the Association, he noted that in Wales £56 and £79 were allotted to hospitals and sanatoriums respectively per bed, whereas in England a substantially higher grant was made. The reason at first given for this disparity was that Wales had many more beds than England. The Chancellor of the Exchequer had recently been interviewed on this matter, and though complete equality between Wales and England had not been conceded, the Government had decided to make an immediate payment to the Association of about £70,000 in respect of money already spent on hospitals and sanatoriums. The announcement was also made that under the provisions of the new National Health Insurance Bill the Association would be deprived of about £25,000 which it had hitherto received from insurance committees in respect of sanatorium benefit. It was not clear how this sum was to be replaced. A report was also submitted by the Research Advisory Committee on the extension of the research branch. The importance of this branch was emphasised, and the hope expressed that a research department would be set up in connexion with the medical school at Cardiff.

Increase or Decrease of Tuberculosis during the War.

Conflicting statements as to the increase or decrease of tuberculosis during the war are still being made, as shown by the following. At a recent meeting of the Essex Insurance Committee the Sanatorium Benefit Subcommittee called attention to the gradual and steady increase in the number of applications for sanatorium benefit from insured persons suffering from tuberculosis. For the first quarter of each of the following years, 1916, 1917, 1918, 1919, and 1920, the applications numbered 96, 122, 166, 190, and 213 respectively. Thus, in 1920, the applications were more than twice as numerous as in 1916. Again, the Countess Ferrers, speaking at a recent meeting of the National Association for the Prevention of Tuberculosis at Finsbury-circus, said that there had been a tremendous and alarming increase of tuberculosis since the war, although before the war the figures were steadily decreasing. Many similar references might be given to alarmist statements made by public speakers, some of whom quoted figures in support of their views. On the other hand, in the *British Medical Journal* for April 24th Sir Robert Philip has drawn attention to the Registrar-General's figures for Scotland. These show that the mortality from all forms of tuberculosis has exhibited a notable fall since the outbreak of the war up to the end of 1919. In 1913 the mortality from all forms of tuberculosis was 170 per 100,000 and 108 from pulmonary tuberculosis. The corresponding figures for 1919 were 129 and 88. It is particularly to be noted that during 1919 there has been a phenomenal drop in both categories—namely, from 158 for all forms of tuberculosis in 1918 to 129 in 1919. The drop in the mortality from pulmonary tuberculosis in the same period was from 107 to 88. Sir Robert Philip draws attention to a similar remarkable drop during the past year in New York State.

Is Sanatorium Benefit Permanent Benefit?

The great improvement in health experienced by the large majority of early cases, and also by a considerable proportion of slightly advanced cases who already have tubercle bacilli present in the sputum, as long as they reside at a well-conducted sanatorium, is well known to all who have had sanatorium experience. Those who can continue to live at a sanatorium as members of the professional or working staff can usually count on continued health and no return of active tuberculosis. Those also in good circumstances, or whose occupation allows them, and who do continue to live an open-air life, with comparatively light employment, have a similar prospect of good health and freedom from disease. Unfortunately, such conditions are not possible for the great majority of those who are granted sanatorium benefit. Dr. D. M. Taylor, tuberculosis officer of Halifax, has recently repeated the oft-told tale of how steadily those discharged from the sanatorium go down-hill.[1] Dr. Taylor attempted to trace the after-history of 85 persons who received sanatorium benefit in 1914. On Dec. 31st, 1919, he found that only 15 were known to be alive, 49 were dead, and 31 could not be traced. Of the 64 traced cases 8 were early and 24 moderately advanced. Six of the early cases and only 6 of the moderately advanced were found to be alive. It is difficult not to conclude that as regards four-fifths of the "benefited" the money spent on sanatorium benefit was for the most part wasted. Dr. Taylor is of opinion that by means of improved diagnosis more early cases must be found, and better after-care provided, assisted by a more sympathetic attitude of employers. He remarks on the futility of advising light out-door work, and rightly states that the ordinary work of the returned case is better than idleness. Large employers could do something in adjusting the work to the man's capacity. A great deal has been done in this way in Woolwich Arsenal for many years with considerable benefit to the returned cases.

Especially since the war the best economic use of sanatoriums has not been made. Personal and sentimental reasons too often sway even tuberculosis officers, and cases are sent to the sanatorium who should be isolated at home or sent to a home for the dying. More than one authority on sanatorium treatment has recommended that in the first place all patients should be admitted for one month only. They should not remain longer unless the medical superintendent reports that they are likely to derive permanent benefit from prolonged treatment. The one month's stay would enable the patient to learn the principles of open air treatment and how to avoid infecting others when he returned home If this recommendation were generally carried out we should get very much better economic results from sanatorium treatment

---

Reports and Journals

The fifth annual report of the Reading Tuberculosis Dispensary Care Association includes an appreciation of the valuable work done by Dr C C Chidell, who acted as temporary medical officer to the Association during the war The report gives details of the various activities of the Association, one of which has been the organisation of a small class for the education of children unfit for ordinary school attendance The class was much appreciated, and marked improvement was shown by those of the children who attended regularly It is greatly to be deplored that the resignation of the teacher responsible for this class has led to its temporary dissolution Recognising the importance of special educational facilities for weakly children, the association has forwarded a resolution to the Education Committee, urging them to provide a residential open air school

In a recent number of the *Medical Record* Dr Stephen J Maher raises the question What has the war taught us of tuberculosis? His answer shows considerable pessimism The war, he believes has made clearer to us the poverty of our equipment for fighting the tubercle bacillus Comparisons, sometimes invidious, between the insufficiencies in equipment of states and countries have inevitably been made Many hundreds of young doctors have learnt the proper use of percussion, auscultation, and the X rays The war has emphasised the need of hospital and sanatorium care for consumptives, and the effectiveness of good nursing and of health propaganda But beyond—nothing The writer maintains that large medical military organisations are not capable of advancing our knowledge of tuberculosis, and that in the future, as in the past, we must put our dependence for results on enthusiastic clinicians and laboratory workers

In the *Wiener medizinische Wochenschrift* for April 29th a report is published of a meeting on Feb 29th of the Gesellschaft für Tuberkuloseforschung The main discussion seems to have centred about Friedmann's turtle vaccine Dr Kollmann and Dr Paltauf demonstrated microscopic sections taken from the skin and subcutaneous tissues in the neighbourhood of an infiltration provoked by an injection of the vaccine in a case of pulmonary tuberculosis Numerous intracellular acid fast bacilli were found in the needle track It did not appear that the injection had been followed by a multiplication of the acid fast bacilli introduced Dr M Weiss had given about 30 injections of Friedmann's vaccine, but had only once seen suppuration follow, and in this case the favourable effect of the injection was not impaired by this complication He rejected the suggestion that tubercle bacilli of the human type were to be found in Friedmann's cultures

CANADA

(FROM OUR OWN CORRESPONDENT)

Canadian Medical Association Annual Meeting

THE fifty first annual meeting of the Canadian Medical Association will be held in Vancouver, B C , from June 22nd to 25th next The president elect is Dr R E McKechnie, Vancouver, who had been elected to the presidency in 1914 when the annual meeting, which was announced to take place at Vancouver, was cancelled owing to the outbreak of the war Dr J W Scane, Montreal, is the acting general secretary, and Dr W A Clarke, Vancouver the local secretary The address in medicine is to be delivered by Dr Charles Lyman Greene, St.Paul, Minn , U S A , the address in surgery by Lieutenant Colonel F Mewburn, Calgary, Alberta, the address in genito urinary surgery by Dr H H Young, Baltimore, Md , U S A At the same time as this meeting there is also to be held in Vancouver the annual meeting of the Canadian Public Health Association, the annual meeting of the Canadian Association for the Prevention of Tuberculosis, the Canadian Committee on Mental Hygiene, the National Committee for Combating Venereal Diseases, and the British Columbia Hospital Association Many prominent medical men are expected at these meetings, not only from Canada but from Great Britain and the United States

Canadian National Council for Combating Venereal Diseases

The first municipal committee of the Canadian National Council for Combating Venereal Diseases was organised in Toronto late in March The meeting was presided over by Mr Justice William Renwick Riddell, and the following officers elected for the Toronto Municipal Committee —Honorary president Mr Justice Frank Hodgins President Dr Frederick W Marlow Secretary Dr Gordon Bates, Toronto The formation of the Toronto committee was coincident with the showing of "The End of the Road, a film drama now being exhibited throughout Canada by the National Council During the five days this "movie was on exhibition in Toronto, some seventeen thousand people attended the meetings, at which public addresses were delivered by prominent speakers engaged by the National Council The general scheme was outlined in which the Dominion and Provincial Governments are combining to deal with the venereal diseases problem in Canada At first the National Council will do general educational work, so that people generally may become aware of the seriousness of the problem, after which the Government treatment schemes are to be conducted in various parts of the Dominion of Canada Local committees are now being formed in many parts of Canada When the National Council has become better organised further educational and social aspects of the venereal diseases problem and treatment-schemes will be considered by the provincial governments

Nutritional Clinics in Toronto

Upon investigation of homes of patients attending the Malnutrition Clinics of the Hospital for Sick Children, Toronto, nurses of the Department of Health have found that the smallest income of the families employing these clinics is $17 50 and the largest $25 00 weekly, whilst the numbers in these families range from four to eight In several of these families there are two or three children attending the clinics, all from 10 per cent to 25 per cent under weight for height Difficulty is found in increasing the milk supply owing to the inadequate income, but it has been common to find families spending their incomes on improper food, defective nourishment being often due to want of knowledge rather than to inadequate income As evidence of the value of the organised activities of a Department of Health, the infant mortality for the five years preceding the present regime or 1904 to 1909 inclusive, was 161 per 1000 births, the infant mortality for the next five years was 140, and in the last five years has dropped to 102 while in 1919 it was only 95

Medical Clinic at Kingston, Ontario

The Kingston Clinical Association Ltd , has been incorporated with a share capital of $100 000 The object of this association is to conduct clinics of a medical character which will supply a standardised systematic examination Specialists in each branch of medicine will be in charge and all modern science equipment will be used This clinic will have the effect of making Kingston, the home of Queen's University and Medical College, a more important medical centre, and may prove a reply to the suggestion that the medical department of Queen's University should move to Ottawa

Physio therapeutic Work in Military Hospitals in Canada

The general plan and scope of the work on physiotherapeutics in the various military hospitals throughout Canada is contained in a report just issued by the Director General of Medical Services for the Dominion of Canada The Canadian Army Medical Corps took over this work from the Canadian Military Hospitals Commission on April 1st, 1918, under which commission undischarged invalided soldiers were being treated in various centres in Canada. At once a systematised scheme for hospital centres in the various military districts throughout Canada was adopted. Provision was made for building accommodation, and as well for a general plan of treatment of the invalided soldier by physio-therapeutic methods either preceding or following surgical operation. Prior to taking over this work the Canadian Army Medical Corps had a report of the methods adopted and apparatus designed and used in the special hospital at Ramsgate, England. The general scheme for treatment departments is based on that which had been found so successful in special hospitals in England. Under this scheme all large hospitals in Canada were divided into active treatment sections, where the actual surgical operative work was performed, and convalescent sections to which the patient was removed after immediate recovery from the operation, and of which these treatment departments formed a part. At least 50 per cent. of all hospital populations required and received some kind of psycho-therapeutic treatment; in special hospitals, such as the Dominion Orthopædic Centre at Toronto, the percentage has been very much higher. To show the amount of work here performed, a return for one recent month may be submitted. In St. Andrew's Military Hospital, Toronto, with a total of 16,095 treatments, they were divided as follows: Massage, 4082; electro-therapy, 1707; radiant heat and diathermy, 454; hydro-therapy, 7350; muscle function training, 676; gymnasium (all classes), 1826. In other institutions in the same recent months the amount of work can be gauged by the figures: Dominion Orthopædic Hospital, Toronto, a total of 11,507 treatments; Manitoba Military Hospital, Winnipeg, 11,399; Camp Hill Military Hospital, Halifax, N.S., 4630; St. Anne de Bellevue Military Hospital, Quebec, 23,265. Summarised: The end of the war has found the C.A.M.C. with the following organisation: A special section in every hospital, particularly devoted to physio-therapeutics, subdivided into active treatment and gymnasium work, working in the closest harmony with the surgical and medical staff.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Official Inquiry into Encephalitis Lethargica in France.

MM. Léon Bernard and Jules Renaut have brought before the Academy of Medicine the results of the epidemiological inquiry of the Ministry of Hygiene into encephalitis lethargica in France. From the 55 departments which have sent a reply 464 cases in all have been reported. The disease seems to attack adults twice as often as children, and people over 60 are only exceptionally affected. Its gravity is undoubted, since the mortality indicated in the reports is at least 30 per cent.; it may be, however, that many mild cases have escaped notice and possibly treatment. Nowhere has the epidemic been very concentrated, it has been sparsely distributed over the country. The cases are so isolated from one another in towns or in the country that most medical men will not admit the possibility of contagion, others suggest that the disease may be propagated, like cerebro-spinal fever, by means of healthy carriers, and of convalescents; in no case has direct contagion been observed. The reports are unanimous in discounting any relation between anterior poliomyelitis and encephalitis lethargica; on the other hand, in nine-tenths of the cases, the doctors point out the coincidence of cases of influenza and of encephalitis lethargica, and emphasise the possibility of a close connexion between these two maladies. It is, at any rate, interesting to note the present decline of the epidemic—70 cases in January, 206 in February, 144 in March, and 44 only in April.

Pseudo-tuberculosis.

Dr. Sergent, of the Hôpital de la Charité à Paris, who since 1914 has examined more than 30,000 soldiers for tubercle, has communicated to the Academy of Medicine an elaborate paper summarising his own careful observations. It emerges therefrom that medical men often regard as signs of early tubercle certain conditions which happily indicate only an impairment of function of the apices, easily curable if precautions are taken, but favourable to the subsequent development of tuberculosis if the subject is placed under bad conditions. Several of the reported cures of tuberculosis doubtless belonged to this category. The facts are of great interest from the recruiting point of view, since it is unnecessary to discard, discharge, or to pension those likely to be cured. The assumption of a probable cure is legitimate when respiratory troubles are limited to the apices. Among these subjects—all adults—there are included many with deformed chests, with adenoids past or present, with narrowed nasal passages, or very often diaphragmatic insufficiency. Radiography shows only deficient air entry in the apical region. Before deciding that these men are victims of early tuberculosis other diagnostic measures should be used, especially as they are often puny, starved-looking, and of light weight. Besides, the bilateral nature of the signs should be noticed, since apical tuberculosis is nearly always unilateral. Confusion should be possible only in the case of a double apical infection, and this usually presents other signs elsewhere.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

On the Social Care and Treatment of Epileptics.

AT a recent meeting of the "Children's Protecting Union" Dr. Frey, professor of nervous diseases, gave a short talk on the care and treatment of epileptics. Among other things, he said that society is wholly responsible for the conditions which are the causes of epilepsy, and it is the duty of society at large to contribute to the care of these unfortunates, who are the victims of conditions created by society. More than 85 per cent. of epileptics are hereditary sufferers, and alcoholism of the parents is responsible for the great majority. It has been said that not less than one of every three children of alcoholic parents suffers from epilepsy. Colonisation of sufferers is the only way in which epileptics can be cared for properly. Dr. Frey said that in most institutions they were thrown with the insane, a condition unfair to both classes of patients. The majority of physicians are willing to admit that purely medical or surgical treatment is of little or no value except in extremely isolated cases. More has been accomplished by a hygienic mode of living, strict regulations of the habits of life, and particularly by suitable, interesting employment and surroundings.

Filth in Country Dairies.

Some shocking conditions have been discovered by Board of Health inspectors in dairies that supply Czernowitz, a city of 200,000 population. In some adjacent villages they have found buildings too filthy for the habitation of cows used for dairy purposes. Wooden floors, rotted with the milk drippings of years, over dank, foul cellars; floors of ill-fitting stone slabs laid on the earth; ancient wooden cooling tanks saturated with filth; open wooden drains and contaminated wells, are among the evils reported after inspection of a hundred small dairies. However, these dairies form only a small percentage of those that send milk to the city. The assistant inspector reported that some of the dairies are excellent in condition, and not a few are as perfect as care and science can make them. The bad cases discovered are worse than anything recently recorded, but they are isolated instances and will be improved or closed up.

Milk and Scarlet Fever.

In a recent report Dr. Popovici, medical officer of health for a large county, traced the origin of a recent spring outbreak of 71 cases of scarlet fever apparently to infected milk. The dairy farm immediately implicated was in good order, but the dairyman had supplemented his own milk by a purchase from a purveyor who obtained his supply from 15 different sources A child of a man employed in milking at one of these was found in a condition pointing to convalescence from scarlet fever Another man's wife was found to have her hands and feet in a state of desquamation Both these persons had been visiting friends in an adjacent town in which scarlet fever was prevalent After the supply of milk from this dairy was stopped no further case of scarlet fever attributable to the dairyman's milk occurred

Malnutrition in Children

In Debretzin Dr Kenezi gave an address on this subject before the Society for the Protection of Children The first cause of the malnutrition of children was, he said, parental ignorance The healthy conditions with which the present parents had been surrounded during childhood had been forgotten by them Breast milk was being superseded by condensed milk and patent foods In many cases this was to be attributed to the fact that during the war thousands of women had to earn their livelihood, and occupied male positions which they retained even at present on account of the exorbitant prices prevailing Though both husbands and wives were in employment they could not secure sufficient income for maintaining their families He said that education was begun too early, and higher education was being overdone, the great social demands made on mothers were taking them away from their children The second cause was found in disease of the children Adenoids and tonsils were familiar examples Disease of the parents was the third cause This was most often lues, an old chancre in the father sometimes expressing itself in the child, as malnutrition without other symptoms If other treatment was tried without result lues should always be suspected, and mercurials and iodides, even neosalvarsan (all borne well by children) should be ordered In general treatment, good sleeping rooms, plenty of fresh air, suitable bed clothing, medium underclothing, plenty of exercise, and a warm bath once a day, should be provided School should not be begun until the seventh year A daily nap should be taken and the child should sleep from 8 P M to 7 30 A M Food should be high in proteids and poor in carbohydrates, and the stomach should be carefully treated Iron, quinine, and cod liver oil were important drugs Malnutrition should always be eliminated, if possible, in the diagnosis of obscure cases

URBAN VITAL STATISTICS.

VITAL STATISTICS OF LONDON DURING APRIL, 1920.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 6·7 per 1000 of the population, estimated at 4,358,309 persons; in the three preceding months the rates had been 8·5, 7·7, and 7·1 per 1000. Among the metropolitan boroughs the lowest rates from these diseases last month were recorded in Paddington, Hammersmith, the City of Westminster, St. Marylebone, Hampstead, Stoke Newington, and the City of London; and the highest in Shoreditch, Bethnal Green, Poplar, Battersea, Wandsworth, and Deptford. One case of small-pox was notified during April from the Port of London. The prevalence of scarlet fever was slightly less than in the preceding month; this disease was proportionally most prevalent in Shoreditch, Bethnal Green, Poplar, Southwark, Deptford, and Greenwich. The Metropolitan Asylums Hospitals contained 1795 scarlet fever patients at the end of the month, against 2476, 2266, and 1981 at the end of the three preceding months; the weekly admissions averaged 223, against 280, 279, and 240 in the three preceding months. Diphtheria was somewhat less prevalent than in April; the greatest prevalence of this disease was recorded in St. Pancras, Shoreditch, Bethnal Green, Poplar, Battersea, and Wandsworth. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1971, 2003, and 1964 at the end of the three preceding months, numbered 1937 at the end of April; the weekly admissions averaged 221, against 263, 240, and 260 in the three preceding months. The prevalence of enteric fever was about half that in the three preceding months; of the 22 cases notified during the month, 3 belonged to Kensington, 3 to Islington, 2 to Marylebone, 2 to Lambeth, and 2 to Wandsworth. There were 29 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 25, 30, and 38 at the end of the three preceding months; the weekly admissions averaged 4, against 4, 6, and 6 in the three preceding months. Erysipelas was proportionally most prevalent in St. Marylebone, Holborn, Finsbury, Bethnal Green, Greenwich, and Woolwich. The 39 cases of puerperal fever included 7 in Wandsworth, 5 in Battersea, 4 in Lambeth, and 3 in Islington. The 21 cases of cerebro-spinal fever included 3 in Islington, 3 in Bethnal Green, and 2 in Southwark, while the 2 cases of poliomyelitis belonged to Lambeth.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended May 1st, the deaths of 5145 London residents were registered, equal to an annual rate of 15·4 per 1000; in the three preceding months the rates had been 14·6, 16·6, and 17·6 per 1000. The

* Including membranous croup.

death rates ranged last month from 9 3 in Chelsea, 10 2 in Hampstead, 12 6 in Wandsworth, 12 6 in Woolwich, 13 2 in Fulham, 13 2 in Lewisham, and 13 2 in the City of Westminster, to 16 9 in the City of London, 16 9 in Poplar, 18 4 in Bermondsey, 18 7 in Stepney, 19 5 in Holborn, 19 9 in Bethnal Green, and 22 3 in Shoreditch The 5145 deaths from all causes included 507, which were referred to the principal infectious diseases, of these, 1 resulted from small pox, 223 from measles, 18 from scarlet fever, 69 from diphtheria, 125 from whooping cough, 9 from enteric fever, and 62 from diarrhœa and enteritis among children under 2 years of age Among the metropolitan boroughs the lowest death rates from these diseases were recorded in Chelsea, the City of Westminster, St Marylebone, Hampstead, Finsbury, and Lewisham, and the highest in St Pancras, Bethnal Green, Bermondsey, and Battersea The death from small pox was that of a Norwegian sailor, and occurred at the South Wharf Shelter of the Metropolitan Asylums Board, situated in Bermondsey The 223 deaths from measles were 27 fewer than the average number in the corresponding period of the five preceding years, this disease was proportionally most fatal in St Pancras, Hackney, Bethnal Green, Southwark, Bermondsey, and Battersea The 18 fatal cases of scarlet fever exceeded the average by 2, and included 3 in Lambeth, 3 in Camberwell, 2 in St Marylebone, and 2 in Wandsworth The 69 deaths from diphtheria were 19 above the average number, the greatest proportional mortality from this disease occurred in Hammersmith, Fulham, Islington, Finsbury, Shoreditch and Wandsworth The 125 fatal cases of whooping cough showed a decline of 18 from the average, this disease was proportionally most fatal in St Pancras Islington, Stoke Newington, Bethnal Green, Stepney, and Poplar Nine deaths from enteric fever were registered during the month, against an average of 5 The 62 fatal cases of infantile diarrhœa were 5 in excess of the average, the greatest proportional mortality from this disease occurred in Paddington, Kensington, Holborn, the City of London, Shoreditch, and Deptford In conclusion, it may be stated that the aggregate mortality in London during April from these principal infectious diseases was 2 7 per cent below the average in the corresponding period of the five preceding years

---

(Week ended May 22nd, 1920)

English and Welsh Towns —In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 14 2, 13 8, and 13 8 in the three preceding weeks, fell to 13 2 per 1000 In London, with a population of nearly 4½ million persons, the annual death rate was 12 0, or 0 5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 4 3 in Eastbourne, 4 5 in Enfield, and 5 4 in Oxford, to 20 3 in Blackburn, 23 7 in Sheffield and 25 2 in Tynemouth The principal epidemic diseases caused 291 deaths, which corresponded to an annual rate of 0 9 per 1000, and comprised 103 from measles, 60 from whooping cough, 56 from diphtheria, 53 from infantile diarrhœa, 14 from scarlet fever, and 5 from enteric fever Measles caused a death rate of 1 6 in Swansea, 1 7 in Wimbledon and in Blackburn, 1 8 in Newport (Mon) and 3 0 in Wigan, and whooping cough of 1 6 in Middlesbrough and 1 9 in Carlisle The deaths from influenza, which had been 202, 201, and 216 in the three preceding weeks, fell to 211, and included 72 in Sheffield, 31 in London, 10 each in Birmingham and Manchester, and 8 in Rhondda There were 1894 cases of diphtheria, 1734 of scarlet fever, and 1 of small pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 1916, 1757, and 6 respectively at the end of the previous week The causes of 31 of the 4491 deaths in the 96 towns were uncertified, of which 4 were registered in Birmingham, and 3 each in London, Liverpool, and Gateshead

Scotch Towns —In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 18 3, 18 4, and 16 9 in the three preceding weeks, fell to 15 6 per 1000 The 375 deaths in Glasgow corresponded to an annual rate of 17 6 per 1000, and included 17 from influenza 12 from measles, 6 each from small pox and infantile diarrhœa, 5 from diphtheria, 4 from whooping cough, and 3 from scarlet fever The 76 deaths in Edinburgh were equal to a rate of 11 6 per 1000, and included a fatal case each of diphtheria and infantile diarrhœa

Irish Towns —The 171 deaths in Dublin corresponded to an annual rate of 21 5, or 0 9 per 1000 above that recorded in the previous week, and included 15 from whooping cough, 6 from measles, and 2 each from infantile diarrhœa and influenza The 124 deaths in Belfast were equal to a rate of 15 7 per 1000, and included 6 from infantile diarrhœa, 3 each from scarlet fever and influenza 2 from diphtheria, and 1 each from measles and whooping cough

HELMINTHIC INFECTIONS IN RELATION TO PELLAGRA.

To the Editor of THE LANCET.

SIR,—I have read with very great interest, in the issues of THE LANCET for May 1st and 8th, the important and suggestive articles on pellagra by Dr. A D Bigland and Dr J I Enright, together with the informing leading article summarising present views in regard to the difficult and debatable question of the ætiology of this disease While Dr Bigland had no need whatever to refer to the quotation of the late Dr Sandwith in connexion with his own article, I am only too conscious that it may be held to apply to my case in venturing to suggest that helminthic infections may constitute a definite ætiological factor in pellagra I am emboldened, however, to take this risk because of the arresting fact, which I learn for the first time from Dr. Enright's paper, that an outbreak of pellagra occurred also among the well fed German prisoners at the beginning of 1919 As stated in the report of the Committee appointed to investigate the outbreak among the Turkish prisoners in the autumn of 1918, there was no occurrence of pellagra among the Germans up to the time when the Committee had concluded its inquiry

When I had the honour of being appointed to undertake the protozoological and other incidental parasitological work for the Commission, I approached the subject of pellagra, which was entirely new to me, with a mind perfectly open and unbiased I mention this, because the first thing that struck me on studying the available literature was the vehement manner in which the partisans of the two chief rival views—namely, the parasitic infective hypothesis and that of dietetic insufficiency—maintained and defended their respective attitudes In the course of my own examinations I obtained not the slightest indication that any protozoan, spirochætal, or other minute organism could be incriminated in connexion with the disease The one finding which did make considerable impression on my mind was the prevalence of helminthic infections, particularly of ascaris, and in a lesser degree of trichocephalus The actual percentage findings of the eggs in the stools of Turkish pellagrous cases were ascaris, 31 5 per cent , and trichocephalus, 21 6 per cent , and, as I state in my own section of the report, "these figures by no means indicate the real proportion of Turkish prisoners infected, which I estimate to have been certainly twice as high and probably more," for reasons there given (Eggs of ankylostomum, it is to be noted, were not found in any case) But I also examined, as controls, the stools of German prisoners in the hospital—men in a nominally normal condition as regards their bowels—and found that they were also infected to a considerable extent with the above nematodes, although in a less degree than were the Turks Ascaris was found in 15 per cent of the stools examined, and here again the actual proportion was undoubtedly much higher This observation surprised me somewhat, because these eggs occurred only most exceptionally in British stools

As a result of my own work and of the entirely negative findings on the bacteriological side I formed the opinion that if any parasite were concerned in the causation of the disease it must be one or more of these very well known intestinal nematodes Could ascaris (say) be regarded as a possible ætiological factor ? I knew that ascaris, as a cause of any general or systemic disturbance, was not usually considered seriously And, of course, there could not be in any case between these nematodes and pellagra the sole binding relation of cause and effect comparable to that obtaining in the case of many microbic diseases Because such helminthic infections are known to occur in many districts and countries where pellagra is never or only rarely met with.

The view I ultimately put forward in the "Summary and Conclusions" of my report was that these nematode infections are to be regarded as an additional or contributory factor in the ætiology of the disease, perhaps especially important as a predisposing cause. I was precluded by the scope of the report from referring to other work or entering into consideration of epidemiological data in connexion with pellagra; but it is not out of place to indicate briefly here the reasons and the train of thought which led me to make the above suggestion. The following is taken largely from that portion of the draft of my report which had—unfortunately, I thought—to be omitted.

Upon consideration of the literature at hand, which dealt mainly with recent work on pellagra in America, I saw that Goldberger's experiments showed, in most definite and convincing manner, that dietetic insufficiency could be a most important, and probably was indeed a decisive causal factor. The point was, was it the only, all-sufficing one? Because, on the other hand, there was a considerable body of opinion which maintained that a deficiency in diet could not be regarded as, at any rate, the sole essential ætiological factor. This school of thought (represented, among others, by Siler, Garrison, and McNeal) considered that some infective agency was also primarily concerned. In support of this view a number of epidemiological data had been brought forward, having reference mainly to the localised distribution of outbreaks and to indications connecting the cases with their immediate environmental surroundings and conditions. It seemed to me that much of this evidence had weight, and that the most reasonable and natural explanation was that offered—namely, the occurrence of some infective agent. It interested me considerably to find that the modern tendency was to abandon the hypothesis of transmission by a biting insect—that is to say, through inoculation—and to favour transmission through the medium of the soil—i.e., the parasite was regarded as an intestinal one, conveyed by accidental contamination of food, drink, and so on. Stress had been laid recently upon a close association of pellagra with inefficient sewage disposal, and it had been stated that improved sanitation in certain districts had been followed by a marked reduction in the incidence of this disease.

I thought that if a nematode infection were implicated it would fulfil admirably every condition required to satisfy the data furnished. There was only one biological point as to which I was a little uncertain (to which reference is made below). Lastly, I read of a statement by Cole which seemed so *apropos* of my idea that I cannot refrain from citing it.[1] Though I am well aware that an isolated observation has little scientific value, it is possible that this one may be of importance in another direction than that indicated by the author. Cole believed that the best treatment for pellagra was the administration of calomel, santonin, and castor oil, and based his faith in these remedies upon the statement of a woman whose three children were suffering from roundworms and pellagra. She gave them vermifuge for the worms, and was surprised to find that not only the worms but also the pellagra disappeared!

I next tried to ascertain what evidence there was of an association between the occurrence of nematodes and pellagra. Very few statistics on this point appeared to have been collected by American workers. The one paper which I could find was by Ridlon, who, in examining the stools of 95 patients, observed *Necator (Ankylostomum) americanum* in 10 and strongyloides in 2; no ascaris eggs were noted. This worker, however, does not appear to have made his observations in the most suitable manner for the detection of eggs. (He emulsified a small portion of the fæces in a large drop of salt solution and examined with an oil-immersion objective. This method will serve quite well for the detection of minute flagellates, for instance, but not nearly enough ground would be covered to say whether eggs were absent or present. I always examined four cover-slip preparations, which contained much more fæcal matter than those made for the detection of protozoa, with a low-power objective.) On the other hand, the frequent association of hookworms and pellagra had been noted in America.

As for Egypt generally, as was well known, the natives are infected to a large extent not only with ankylostomum, but with ascaris, and pellagra is rife amongst them. Indeed, Sandwith and Pell have suggested that the presence of helminthic infections may be a more important contributory factor in the causation of pellagra than has hitherto been thought. The prevalence of a specific ascaris infection is referred to by Dr. R. G. White, of the Public Health Department, Cairo, in his report on the outbreak of pellagra in the Armenian Refugee Camp at Port Said in 1916-17. And Professor W. H. Wilson himself informed me that during a heavy pellagra season in 1917 in the Egyptian convict prison at Tourah (?), a large percentage of ascaris infections was observed. As regards Italy, it has been stated (Blanchard) that nematode infections are general and widespread; and Low and Sambon have remarked that a distinct eosinophilia is frequently noticeable in cases of pellagra. In short, the cosmopolitan distribution of such nematodes as ascaris would agree perfectly well with the distribution of pellagra, which is now becoming recognised as almost cosmopolitan, even though, in some districts, its occurrence is rare and sporadic. The coincidence is, at any rate, very much closer than in the case of pellagra and any particular variety of biting-fly.

At this stage I laid the results of my observations, and the opinion at which I had arrived, before Major A. Ferguson,[2] under whose general direction, as head of the Bacteriological Laboratory Service, E.E.F., my work was carried out. He kindly offered to introduce me to Major F. H. Stewart, I.M.S., then in Cairo, in order that I might ascertain directly the latest known facts concerning the biology of ascaris, and the views held as to its pathological effects. I wish very much to thank Major Stewart for the information he gave me, both then and in a more recent conversation which I have been able to have with him.

The point about the biology which I was particularly anxious to know was whether the eggs, if ingested by another man shortly after being passed in the fresh fæces, would develop. Major Stewart's answer was decidedly in the negative. The eggs, unripe when passed, require, for the development of the embryo, to spend a period of time in a moist situation, with free access to air; otherwise they are not infective. The importance of this fact is at once recognised in connexion with the so-called crucial transmission-experiment of Goldberger, in which this author claimed to have shown by feeding volunteers with all manner of materials from patients that there was no transmissible factor concerned in pellagra. Precisely with regard to ascaris (and quite likely other nematodes as well), the experiment would fail, for the above reason, although eggs might be present in the fæces! But the pollution of damp soil, together with untidy habits, would be the surest means of bringing about contaminative infection. Much, also, has been made of the argument that as attendants on patients suffering from pellagra (in institutions, &c.) do not thereby become themselves pellagrous the disease is not "infectious"; but, again for the above reason, neither would they, if of cleanly habits, contract a nematode infection.

With regard to the effects of ascariasis, I was impressed by finding that Major Stewart took a more serious view of these than I had thought likely. The gist of what he told me has been succinctly stated by him in a recent paper[3] in the following words: "It may be doubted whether the importance of this disease [i.e., intestinal ascariasis] is sufficiently recognised in State medicine. There is reason to suppose that a great deal of the debility of the natives of the tropics is due to ascariasis, and that this disease is at least equal to ankylostomiasis in economic importance."

The above, then, were the data which led me to put forward a view which might be regarded as a combination of the two chief hypotheses. I suggested that, in addition to one essential factor, deficient nutrition, another might be necessary—namely, the presence of a helminthic infection, either as a predisposing or as an associated cause. (I thought it quite likely that more than one of these nematodes, e.g., ankylostomum, as well as ascaris might be implicated.) However, if I may so express myself, the general atmosphere in which the Commission was by now labouring was so favourable and conducive to the rapid and luxuriant growth of the dietetic-deficiency hypothesis that any other little plant had scarcely room to raise its tender little head, still less to thrive. In other words, biologic protein value (B.P.V.) deficiency was by this time regarded as of itself an all-sufficient explanation, the one essential causative factor, and, indeed, it certainly did seem fully capable of explaining all the facts relating to the outbreak amongst the Turkish prisoners of war. Hence, as a one-factor hypothesis appeared sufficient, it seemed to the Commission unnecessary to include any other factor in possible explanation of the ætiology of the disease, and the Commission did not support me in thinking that any direct or special importance might be attached to the occurrence of helminthic infections in this connexion.

---

[1] Abstract in Trop. Dis. Bull., vol. viii, 1915, p. 347.

[2] I desire to take this opportunity of saying how greatly I feel I am indebted to the late Major Ferguson for all his valuable assistance and the unfailing consideration which he showed to me while I was with the E.E.F. By his death medical science in Egypt has suffered a severe loss. Merely to read his report of the work done by himself and Captain Campbell for the Pathological Section of this same Commission, a report which was written while he was actually far from well, is to gain instant appreciation of the excellence of his work. Not only as a scientific statement, but also on account of its literary style, this analysis compels one's admiration.

[3] Parasit., 10, 1918, p. 197.

As stated at the commencement of this letter, I am induced to bring forward again the above view because of the remarkable fact that pellagra occurred subsequently among the well-fed German prisoners. According to Enright, there can be no question that the diet of the Germans possessed an adequate B.P.V. This being so, it does appear to me that—to pursue the above simile—the robust plant so well nourished and watered in Cairo outgrew its strength and is in need of pruning. Its growth was perhaps a trifle too rampant, that is all. Because it can hardly be doubted that this plant will prove most productive of valuable fruit. As the review in THE LANCET points out, the work of the dietetic and biochemical sections of the Commission will provide a landmark in the history of the ætiology of pellagra. Therefore, I think Enright is far too hasty in saying that the *food deficiency "theory"* is "exploded", but he himself has distinctly qualified this statement in a preceding sentence. On the other hand, I entirely agree with him in thinking that, as the *only* essential causative *factor*, this hypothesis is seriously threatened. "Obviously, something more than a dietetic factor is involved," and I myself am now still more strongly of the opinion that this *additional factor may well be a helminthic infection.*

Consider the case of these German prisoners. Even though it is quite likely that some of those who became pellagrous had defective digestive assimilation as a result, say, of precedent bacillary dysentery, that factor, as Enright clearly points out, could not of itself account for an outbreak of pellagra. Now, what other possible factor had the Germans in common with the Turkish prisoners? They had a prevalent nematode infection, well marked, if not to such a high degree as in the case of the Turks. Again, since the well-fed Germans contracted pellagra, why did this disease never occur among the British troops? Was it because there were practically no intestinal helminthic infections amongst the latter? During my sojourn in the East I examined altogether something like 5000 British stools and during the whole period of nearly three years at no time were eggs found except on the rarest occasions; their occurrence was so exceptional that I did not consider it necessary to keep any figures. But I see that O'Connor has tabulated the helminthic infections found in the course of his examinations of British stools.[4] Out of 2082 cases he observed ankylostomum in 1, trichocephalus in 9, and ascaris in 0! Adding them all together the percentage is under 0.5; doubling or even quadrupling this figure (for under-estimation) the percentage is still only 1 or 2. Contrast this British percentage with my estimate of anything up to at least 30 per cent. of ascaris alone in the case of the Germans I examined. Is it not likely that this great difference has some significance?

I wish now to refer, although with much diffidence, to another side of the question. In the first place, the fourth conclusion arrived at by Colonel F. D. Boyd, in his valuable report on the clinical aspect of pellagra as seen among the Turks, is stated as follows:—

> "The clinical features of the disease are those of a profound suprarenal inadequacy, but there is no sufficient evidence to prove how this inadequacy is produced."

I abstract next the following sentences from Dr. Bigland's paper:—

> "This brings me to the second supposition regarding the ætiology of pellagra—viz., the presence of some toxic substance. I would suggest that such a toxin is present in these cases, and that it acts upon the intestines or the contents thereof in such a way that protein is not assimilated as it ought to be. . . . It only remains to discuss what is the nature of this hypothetical toxic substance. It must enter the body from without. It cannot be the result of a metabolic error, because the disease occurs in epidemics. Its probable habitat is the digestive tract. . . . *It may be, however, that this toxic substance makes its effect by attacking the endocrine organs, especially the suprarenals.*" (the italics are mine).

On reading this, the question naturally occurred to me, Could ascaris and other nematodes produce such a toxin? Major Stewart informed me that ascaris certainly does produce a toxin, and on looking up to see if any work had been done upon the specific effects produced by such a toxin, I came across a paper by Phillips Bedson, upon "*Lésions des organes à sécrétion interne dans l'intoxication vermineuse.*"[5] Certain of the observations made in the course of this experimental work seem to me sufficiently important and suggestive to justify my bringing them to the notice of any who may think such a line of research is worth following up in relation to pellagra.

> Bedson injected into guinea-pigs the (sterile) peri-enteric liquid (presumably the hæmocœlic fluid) of *Ascaris megalocephala* and filtered extracts of different species of tænia. The author's account is divided into two parts. One part deals with the effects of acute helminthic intoxication produced by intravenous injection of a single dose of the above toxic liquid, the other with the effects of chronic intoxication produced by successive daily doses (smaller in amount) given subcutaneously (for fuller details the reader is referred to the original). As regards the chronic intoxication the animals did not all react in the same manner to the injections. Some remained in good health, while others became emaciated and lost weight, the loss varying in general with the duration of the experiment. The lesions were the same whether the toxic liquid was from ascaris or from tænia. Of all the ductless glands the suprarenals showed the most important lesions, whether as a result of acute or of chronic intoxication. The thyroid gland reacted equally, but chiefly to subacute or chronic intoxication. The importance of the lesions was related rather to the number of the injections and *duration of the intoxication than to the quantity of toxin injected.*
>
> Dealing with the effects of chronic intoxication on the suprarenals the author states that at autopsy these glands were found to be congested, sometimes intensely. The lesions varied according to the manner in which the animal had reacted to the toxin. Sometimes the glands were found to have recovered from the attack (as it were)—i.e., reacted to the first injection and showed after the lapse of some *time manifest signs of hyperfunction; in the other cases the suprarenals had not been able to resist the action of the toxin and had remained in a condition of hypofunction.*

Is it possible, I would ask, that some of these helminths produce similar effects, even though perhaps in lesser degree, on the human suprarenals as a result of the secretion or excretion by the worm of some substance, or product of metabolism which is toxic? Admitting this possibility, the power of the suprarenal glands to react successfully to the toxic principle may vary considerably also in the human organism, as Bedson found in the case of the guinea-pig. If this be so, it will be clear, I think, that a helminthic infection might be, under certain conditions and especially when associated with dietetic insufficiency, *one very important factor in causing suprarenal* inadequacy and pellagra.

In conclusion, I will quote Dr. Bigland's expression of opinion: "It must not be thought that the disease is a clinical entity in the sense that it has one definite cause only in its production. It may be of the nature of a syndrome for which more than one factor may be responsible. In some cases the importance of one factor (e.g., B.P.V. deficiency) may predominate, in others that of another factor (e.g., helminthic intoxication), while in still others both factors may be equally important."

I am, Sir, yours faithfully,

H. M. WOODCOCK, D.Sc. Lond.,

Lately Protozoologist to the Committee of Inquiry into the
Prevalence of Pellagra among Turkish Prisoners of War.

Lister Institute of Preventive Medicine, Chelsea-gardens, S.W.,
May 18th, 1920.

SPECIFICITY AND EVOLUTION IN DISEASE.

To the Editor of THE LANCET.

SIR,—I was very much interested in reading the historical retrospect on the above subject by Sir William Job Collins in THE LANCET of May 15th. In my last annual report to the Education Committee, writing in reference to the condition of the children attending the elementary schools, on my return to duty after some four years absence, I said that—

> "Owing to various causes, such as stress of the war, the food difficulty, shortage of staff, outbreaks of various diseases, &c., the health of the children and teachers has obviously suffered in many cases ...... in this connexion I might mention that the children attending the schools on the high ground at the back of St. Leonards and Hastings appeared in better health than those in the valleys. In reference to the food question, apparently the majority of children had sufficient in bulk, but it was deficient in quality, and certain essentials, such as fats and sugar, which to my mind are most important constituents for a growing child, were reduced to a minimum. ...... Personally, I am inclined to think the present epidemic of skin troubles, from which so many of the children are suffering, is in some measure due to the alteration in the diet, since it is possible owing to the constituents of the tissues themselves having become modified they are less able to withstand attacks of infective organisms; also certain microbes which are usually harmless have been able to take on pathogenic properties owing to such modification of the body tissues. The same cause might also account for other epidemics which have been so prevalent during the past year or two."

I made the above remarks with a view to emphasising the fact that certain defects among the children were apparently the result of evolution, brought about by abnormal conditions.

In another part of my report I make the statement:—

> "Children do not always eat sweets on account of their attractive taste, but to supply a physiological want, more especially owing to the present shortage of sugar."

Here, again, I believe that sugar and also fats play a most important part, from the point of view of evolution, in the history of a race, not only as regards diet, but as a prophylactic against disease.

In reference to other diseases, viewed in the light of evolution, many intricate pathological conditions might find a rational explanation. Take, for instance, the ætiology of cancer, might not this be due to an attempt at asexual reproduction on the part of nature at a time of stress? Similar phenomena are known to take place in the lower forms of animal life.

I am, Sir, yours faithfully,
O. POLHILL TURNER, D.P.H. Oxon.,
Hastings, May 18th, 1920. School Medical Officer.

THE FEE FOR CONDUCTING AN AUTOPSY.

To the Editor of THE LANCET.

SIR,—Would it not be a good thing to make an effort to get the fee paid for making a post-mortem examination by order of a coroner increased? A fee of one guinea was, to say the best of it, small before the war. It is now miserably inadequate. A post-mortem examination cannot be properly made in under an hour. It has to be performed at short notice and often at an inconvenient time. It requires considerable skill to perform and to draw the right conclusions from it. In the country there are none of the facilities of a city mortuary, no skilled assistance, and very often no proper cleansing accommodation. In fact, in the country it is often hard to find anything which can be said to really facilitate the examination. I think very few will suggest that if the present fee were trebled it would be excessive. I am, Sir, yours faithfully,

Weybridge, May 20th, 1920. J. W. ROB.

THE BRITISH SCIENCE GUILD.—The annual meeting of the British Science Guild will be held at the Goldsmiths' Hall, Foster-lane, London, on Tuesday, June 8th, at 3 P.M. Lord Sydenham, G.C.S.I., F.R.S., in vacating a presidency marked by two successful Scientific Products Exhibitions, will deliver an address on "Science and the Nation," and this will be followed by an address on "Some National Aspects of Transport" by the incoming President, Lord Montagu of Beaulieu, whose contributions to mobility of many types in India and at home seem likely to be succeeded by illustrations of mobility of quite another type in the urgent and important application of knowledge to national affairs. Applications for invitations to the meeting should be addressed to the Secretary of the British Science Guild, 6, John-street, Adelphi, London, W.C. 2.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—Examinations for the Diplomas in Psychological Medicine and Ophthalmic Medicine and Surgery of the Royal Colleges of Physicians and Surgeons will commence on June 28th and July 26th respectively. Full information can be obtained from the Secretary, Examination Hall, 8, Queen-square, Bloomsbury, W.C.1.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At the special and ordinary First Professional Examination for the diploma of Fellow, held from May 4th to 15th, 168 candidates presented themselves, of whom 74 were approved and 94 were rejected. The following are the names and medical schools of the successful candidates:—

A. L. Abel, Univ. Coll.; H. H. Bailey, London Hosp.; J. A. Berry, Guy's; O. Brenner, Birmingham Univ.; R. St. L. Brockman, St. Bart.'s; D. J. Browne, Sydney Univ. and Middlesex; A. G. Bryce, Manchester Univ. and Middlesex; W. F. Christie, Edinburgh Univ.; E. A. Coldrey, St. Bart.'s; S. H. Cookson, Birmingham; V. M. Coppleson, Sydney Univ. and Middlesex; H. Corsi, St. Bart.'s and St. Mary's; R. K. Dadachanji, London; R. M. Dannatt, St. Bart.'s; W. M. Dickson, Edinburgh Univ.; T. F. M. Dilworth, St. Thomas's; C. F. T. East, Oxford Univ. and King's Coll.; J. A. W. Ebden, Westminster; D. J. Evans, Birmingham Univ.; G. I. Evans, St. George's; W. C. Faull, St. Mary's; A. W. Fawcett, Bristol Univ.; L. R. Fifield, London; W. D. Galloway, Guy's; A. T. Gibb, Manchester Univ.; J. W. Gilbert, Bristol Univ.; P. K. Gilroy, Cambridge Univ. and St. George's; V. B. Gokhale, Bombay and Middlesex; E. Grey, Manchester Univ. and Middlesex; A. R. Gunn, Edinburgh Univ. and St. Bart.'s; S. G. Harrison, St. Bart.'s; F. H. Healey, Birmingham Univ.; S. L. Higgs, Cambridge Univ. and St. Bart.'s; J. P. Hosford and R. W. P. Hosford, St. Bart.'s; F. Hudson, Univ. Coll.; J. B. Hunter, Cambridge Univ. and Univ. Coll.; I. B. Jose, London; N. J. Judah, Edinburgh Univ.; G. L. Keynes, Cambridge Univ. and St. Bart.'s; J. Le M. Kneebone, London; E. A. Linell, Manchester Univ.; S. D. Lodge, Leeds Univ.; J. Love, Middlesex; W. M. H. McCullagh, Queen's Univ. and Middlesex; A. C. Maconie, St. Bart.'s; N. S. Macpherson, St. Thomas's; W. C. B. Meyer, Edinburgh Univ. and Univ. Coll.; P. J. Moir, Glasgow Univ. and London; O. G. Morgan, Guy's; D. F. A. Neilson, St. Thomas's; R. L. Newell, Manchester Univ.; H. G. Oliver, London; L. F. O'Shaughnessy, Durham Univ.; S. T. Parker, Otago Univ. and Middlesex; Eleanor Joyce Partridge, Lond. Sch. Med. for Women; D. H. Patey, Middlesex; C. V. Patrick, St. Thomas's; P. P. Pughe, Univ. Coll.; F. H. Scotson, Manchester Univ.; S. C. Shanks, Glasgow Univ.; E. S. S. Smalpage, Sydney Univ.; J. F. H. Stallman, Guy's; C. Sturton, Cambridge Univ.; C. H. Terry, St. Bart.'s; C. P. Thomas, Cardiff and Westminster; J. W. T. Thomas, Middlesex; A. H. C. Visick, St. Bart.'s; E. Watson-Williams, Cambridge and Bristol Univs. and Middlesex; H. P. W. White, Edinburgh Univ.; H. A. B. Whitelocke, Middlesex; O. H. Williams, Edinburgh and Liverpool Univs.; A. D. Wright, St. Mary's; and H. B. Yates, St. George's.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—A quarterly meeting of the Royal College of Physicians was held on May 4th, Sir Robert Philip (President) in the chair. Dr. Andrew Graham Ritchie was elected a Fellow of the College. Dr. George Sandison Brock, M.B.E., Dr. Chung Yik Wang, and Dr. Thomas Frederick Corkill were elected Members of the College. The Lister Fellowship for Original Research was awarded to Dr. G. W. Marshall Findlay.

Parkin Prize.—This prize of £100 is open to competitors of all nations. The subject of the essay for the present period is "On the Curative Effects of Carbonic Acid Gas or Other Forms of Carbon in Cholera, for Different Forms of Fever and Other Diseases." Essays intended for competition, which must be written in the English language, to be received by the secretary not later than Dec. 31st, 1920.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—*At a meeting of the College held on* May 19th the following candidates, having passed the requisite examinations, were admitted Fellows:—

John Stanley Arkle, Cyril Victor Baigent, Harry Banks, Max Richard Boe, August Lyle Buchanan, Charles Henry Corbett, Pares Chandra Datta, John Newbury Fraser Ferguson, Frank Cyril Greig, Edward Wilson Hall, Arthur Dodsworth Haydon, Ashley Ernest Herman, William Henry Johnston, Gideon Johannes Joubert, Charles Hardiman Laver, Arthur Poole Lawrence, Crichton Raoul Merrillees, Ronald Kelburne Merson, Ryder Percival Nash, John Millie Pringle, Frank Hubert Robbins, Harold Farley Seymour, Frederick Montgomery Spencer, Robert Stevenson, Claude Bartley Tudehope, Cuthbert Arnold Verge, Rankin Greig Walker, Andrew Walbrugh, Norval James Watt, Harold Williamson, and Gordon Stewart Woodman.

The following candidates, having passed the requisite examinations, had the Higher Dental Diploma conferred upon them:—

Douglas Llewellyn George Radford, Charles Henry Kemball, and James Dalgleish Hamilton Jamieson.

At the same meeting the Bathgate memorial prize, consisting of bronze medal and set of books, was, after a competitive examination in materia medica, awarded to Mr Herbert John Appleyard The Ivison Macadam memorial prize in chemistry, consisting of bronze medal and set of books, was awarded after competitive examination, to Mr Leonard Alexander Watson

UNIVERSITY OF MANCHESTER —At the recent meeting of the University Court it was stated that the number of students attending the University is 2778 nearly double that of 1914-15 In the Faculty of Medicine alone the number has risen from 270 in 1913 to 766 at the present time There are now 574 women students in the University The University appeal launched in December makes progress, but the half way point towards the £500 000 asked for has not yet been reached the amount at present promised touches £200 000 The Vice Chancellor, Sir Henry Miers, said recently—

> Some people may have thought that the University has been doing in some respects an undignified thing in having a startling press campaign I am inclined to think there is no other way nowadays of approaching the main mass of the population in a great industrial district like this but through the press At any rate one effect of this campaign is that the University and its needs are certainly well known throughout the whole district and there is no excuse for anyone to say they have never heard of the existence of the University or of the difficulty under which it carries on its work

THE VOLUNTARY HOSPITAL AND THE REMUNERATION OF THE STAFF —A conference of representatives of the honorary visiting staffs of some of the larger voluntary hospitals of the Midlands was held at the Leicester Royal Infirmary on May 18th The hospitals represented included those of Birmingham, Burton, Coventry, Derby Leicester Loughborough, Manchester, Northampton Nottingham Salford, Sheffield, Stoke on Trent West Bromwich, and Wolverhampton Thirty six representatives were present The chair was taken by Sir Richard Luce, of Derby The questions brought up for discussion were —

1 The desirability of payment for the visiting staff for work done at their hospital on behalf of the Ministry of Pensions the Ministry of Health or the local medical health authorities and if so at what rates

2 Whether the time has come to ask for payment for the visiting staff for all work done by them at the hospitals and *if so* whether this should take the form of an honorarium a salary or a percentage of the expenses of the hospital

If not what alteration in the existing management or financial arrangements of the hospitals would create the need for such a request

After full discussion the following resolutions were passed —

1 That payment for the visiting staffs was desirable for work done at their hospitals on behalf of the Ministry of Pensions the Ministry of Health or for the local medical health authorities

The question of methods and rates of pay was referred to a committee for detailed consideration and report

2 That the time has not come for visiting staffs to ask for payment for all work done by them at the hospitals

It was felt, however, that the need for such a request would arise if the State or local authorities should assume control over the hospitals or if the income of the hospitals ceased to be derived from voluntary contributions No definite organisation was formed for future meetings but the chairman and secretary to the meeting were instructed to reassemble the conference at their discretion

HEALTH EXHIBITION IN BELFAST —A health exhibition collected together by the Women's National Health Association of Ireland (of which the Marchioness of Aberdeen was the foundress) was opened in the Ulster Hall Belfast on May 17th, by the Countess of Shaftesbury, under the auspices of the Public Health Committee of the Belfast City Council and the Council of Social Welfare and has since been largely attended In connexion with it an address on "Housing" was given on the evening of May 17th by Sir Crawford McCullagh (chairman of the Belfast Housing Committee) which showed that the whole difficulty arose from the high price of materials and from the rising wages of workers On the next evening May 18th an address was given by Sir John Byers on Mother and Child, in which special emphasis was laid on the importance of providing more maternity beds available for serious obstetric cases and for those living in crowded dwellings and on the evil of separating mother and child, as exemplified in the high illegitimate infantile mortality rate On May 19th the lecture on Tuberculosis was given by Professor J A Lindsay in which special attention was drawn to better civilisation as a factor in preventing tuberculosis and to the awful condition of the national schools in Belfast, some of which he said would be a disgrace to the Soudan Mr R J Johnstone on May 20th lectured on The State and Public Health While strongly approving of the State taking more to do with the public health, he expressed himself as being totally opposed to a State medical service On May 21st Mr D Houston of the Irish Agricultural Society lectured on Milk, and brought out the importance of healthy cows and of clean dairying

TUBERCULOSIS SOCIETY A REPRESENTATIVE CONGRESS —Under the auspices of this society a two-day Congress was held in Leeds on May 13th and 14th, with additional meetings at Bradford and Harrogate on the 12th and 15th The Congress was representative of tuberculosis workers from all parts of the country, including Ireland The preliminary meetings in Bradford were addressed by Dr Nathan Raw, M P who outlined the proposals of the Government with regard to industrial settlements, Mr H Thornton Pullan (chairman of the Bradford Health Committee) Dr H Vallow (tuberculosis officer, Bradford), Dr H de Carle Woodcock (the President), and others The chief substance of these meetings was devoted to the need for better housing and the necessity of a clean milk supply On Saturday May 15th, delegates visited Harrogate, where they were entertained to luncheon, and visited the baths

ASSOCIATION OF PHYSICIANS OF GREAT BRITAIN AND IRELAND —The thirteenth annual meeting of this association was held at the University of Manchester on May 21st and 22nd Dr Judson Bury was in the chair, and about 100 members attended At the business meeting Dr Judson Bury was selected as President The honorary treasurer (Sir William Hale White) and the honorary secretary (Dr H Morley Fletcher) were re elected the latter having recently succeeded Sir Wilmot Herringham, who has retired from office to the great regret of the members The Executive Committee consists of these officers and of Drs Charles T R Elliott W Pasteur, and Professors Arthur J Hall and J Russell representing England Dr Francis Boyd and Professors Ashley Mackintosh and R Stockman to represent Scotland with Drs J E MacIlwaine, Gilman Moorhead and G Peacocke to represent Ireland Birmingham was selected as the place of meeting for next year The meeting was in every respect a successful one but the rules of the Association preclude any report of the proceedings Special thanks were accorded to the local honorary secretary, Dr A Ramsbottom who had made excellent arrangements for the comfort of the visiting members

THE MEDICAL DEFENCE UNION INCREASE OF SUBSCRIPTION —At a special general meeting of the Union held at the Medical Society of London 11, Chandos street London, W on May 20th the following resolutions were carried —

> That on and after the 1st January 1921 the annual subscription to the Medical Defence Union shall be £1 which payment shall provide each member with indemnity against damages and costs awarded against him to the extent of £2500 in any case which is undertaken on behalf of the member by the Medical Defence Union and that a member elected on or after the 1st July in any year shall pay half the current subscription for that year
>
> That the fee for life membership shall remain at £25 which payment shall include all the benefits of the indemnity on and after the 1st January 1921 Life members who have compounded for a less sum and are still in practice shall be asked to pay a subscription of 5s per annum to cover the indemnity

Newly registered medical practitioners will be admitted to membership on and after Jan 1st 1921, without payment of an entrance fee provided that they join the Union within one year of the date of their registration

VITAL STATISTICS FOR CALCUTTA —The total number of deaths registered in Calcutta during the week ending April 10th was 716 against 707 and 667 in the two preceding weeks, and lower than the corresponding week of last year by 315 These are the figures given by Dr H M Crake health officer There were 64 deaths from cholera against 48 and 47 in the two preceding weeks the number is lower than the average of the past quinquennium by 57 There were 13 deaths from plague against 4 and 3 in the two preceding weeks, the average of the past quinquennium being 19 There were 80 deaths from small pox during the week against 114 in the previous week There were 30 deaths from influenza against 36 in the previous week The mortality from fevers and bowel complaints amounted to 55 and 70 respectively, against 70 and 71 in the preceding week The general death rate of the week was 41 6 per 1000 per annum, against 37 4 the mean of the last five years There were 45 imported deaths Excluding these the death rate of the city was 38 1 There were 160 deaths from respiratory diseases against 150 in the previous week

GENERAL REGULATION IN AUSTRIA OF MEDICAL FEES —One of the chief aims of the medical organisation in Austria has been achieved within the last few weeks in the approval of the new schedule of medical fees by the medical council elected for this purpose The system now in force provides for the differences of the cost of living in towns or in the country, as the value of money is quite different according to the place in which the doctor resides The scale will rise from a minimum of five times the sum charged before the war Thus the minimum fee payable for a call at the patient's house in Vienna will be 30 kronen in daytime and 100 at night This sounds much, but is really very little, as its buying value is not more than about 1s. and 3s. respectively. Of course, this minimum fee is to be charged only to the poorer classes of patients, the wealthy being expected to pay more. Still, the impoverishment of the people has attained such a degree that the profession will have much difficulty in obtaining fees corresponding to the general rise of food prices. One feature of the scale recommended for general adoption is the relation between the minimum fees of the general practitioner, the better qualified man (privat-docent or specialist), and the professor as 1 : 2 : 4. These figures are also meant to be a minimum. Every medical or surgical interference besides a simple examination—i.e., a hypodermic injection, the washing out of an organ, the application of a bandage, or the instillation of drops—is to be charged for extra.

CENTRAL MIDWIVES BOARD.—A special meeting of the Central Midwives Board was held at Queen Anne's Gate Buildings, Westminster, on May 20th, with Sir Francis H. Champneys in the chair. Two midwives were struck off the roll, the following charges amongst others having been brought forward:—

1. Being in attendance at a confinement and the child suffering from dangerous feebleness the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rule E. 21 (5); the child being in the condition aforesaid, she neglected to hand to the husband or the nearest relative or friend present the form of sending for medical help, properly filled up and signed by her, in order that this might immediately be forwarded to a medical practitioner or to an approved institution, as required by Rule E. 20; the death of the child having occurred before the attendance of a registered medical practitioner, the midwife neglected to notify the local supervising authority thereof, as required by Rule E. 22 (1) (b), and she neglected to take and record the pulse and temperature of the patient at each visit, as required by Rule E. 14.
2. The midwife did not enter her records of the pulse and temperature of her patients in a notebook or on a chart carefully preserved, as required by Rule E. 14. A child suffering from serious skin eruption during her attendance the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rule E. 21 (5), and the patient suffering from a condition supposed to be infectious, the midwife neglected to send any notification to the local supervising authority of the fact, or that she was herself liable to be a source of infection, as required by Rules E. 6, E. 22 (1) (e), and E. 23 Form (e).

Parliamentary Intelligence.

HOUSE OF LORDS.

National Health Insurance Bill.

ON Monday, May 17th, on the motion of Viscount ASTOR, the National Health Insurance Bill was read a second time. On May 18th, on the motion that the House do go into Committee on the National Health Insurance Bill, the Marquess of SALISBURY complained that the Bill, which contained 21 clauses, most of their legislation by reference, had been rushed through the Standing Committee at one sitting and passed the Report and Third Reading stages in the House of Commons at an all-night sitting. Was it possible to treat Parliament with greater contempt? He moved the adjournment of the debate in order to hear what explanation the Government had to offer.—Viscount ASTOR said the Bill was most urgent. Over 2,000,000 cards had to be filled in, registered, and distributed among the Approved Societies, and unless that were done immediately it was impossible for those societies to be ready by July 1st, when the next half-yearly contributions were due. In addition to that, if the Bill were not passed before Whitsuntide a serious additional burden would be laid upon the Treasury. —The Marquess of SALISBURY, in withdrawing his motion, said he hoped that the proceedings that afternoon would convince the Government that they were no longer to assume that the House of Lords would always be ready to pass Bills sent up from the Commons at the very last moment.—The Bill passed through Committee, was read a third time, and passed. The Bill received the Royal Assent on Thursday, May 20th.

HOUSE OF COMMONS.

MONDAY, MAY 17TH.

Medical Services in the Navy.

The House went into Committee of Supply on the Navy Estimates for 1920-21, Sir E. CORNWALL in the chair. On a vote of £677,300 for the expense of medical services, including the cost of medical establishments at home and abroad,

Sir D. MACLEAN said there could be no doubt at all that the Committee welcomed any further efficiency, and, indeed, any reasonable addition to the cost of the medical services of the navy; but he would point out that, while the numbers to-day were identical with those in 1912-13, the cost had risen from £279,000 in the latter year to £677,000 in this Vote. He knew that the prices of medical stores had soared almost beyond the range of percentages, but on the question of numbers he did wish to elicit some information. As far as he could see on the medical establishments at home and abroad there had been this year no reduction at all in numbers. While under Vote A the number of officers and men for the Royal Navy had fallen from 225,000 to 126,000, on the medical establishment there had been no corresponding reduction. Why was it that they still required 3 surgeon rear-admirals, 8 surgeon-captains, 17 surgeon-commanders, and 43 surgeon-lieutenants? He noticed that there was some reduction in the nursing staff, and that the cost there had gone down from £34,300 last year to £30,700 this year. But there was a greater charge for the rear-admirals, whose numbers were diminished, of £50. There was a slight increase in the charge for surgeon-captains, while that for surgeon-commanders had risen from £16,900 to £18,400.

Sir T. BRAMSDON complained that certain unqualified ratings were actually placed in charge of hospital wards in order to allow leave to members of the staff. He also asked if the Medical Director-General had yet paid a visit to the Royal Naval Hospital at Haslar to see what the situation was there.

Lieutenant-Colonel KENWORTHY said in 1919-20 they voted a sum of £9500 on account of the expenses of two hospital ships; this year the sum was £40,270. He suggested that these hospital ships might well be employed in assisting the army to bring home sick British soldiers from Egypt. If they were employed on any other service which prevented them from doing that, and which was not a purely British naval service, the Committee ought to be informed.

Sir J. CRAIG (Financial Secretary to the Admiralty) said they were getting back—slowly in some cases, more rapidly in others—to what they hoped would be a satisfactory state of finance, but it could not be done suddenly. They had still on hire at the moment two hospital ships, which they were going to replace, probably by purchase. Where their services were required, there those ships should be in accordance with naval policy. In reply to Sir D. Maclean, he might say that the personnel afloat was paid for out of Vote 1 and not out of Vote 3, but he admitted that something might be done to make the estimate a little clearer in this respect, and he would promise to meet his right honourable friend's wishes with regard to that. In reply to Sir T. Bramsdon, if a visit by the Director-General to examine into the affairs at Haslar Hospital was necessary it would be arranged as soon as possible.

Viscount CURZON said that before the war the position of hospital ships in the navy was not very satisfactory, and he hoped that a definite policy would be laid down with regard to them. He had noticed that in certain naval depôts and naval establishments the medical staff had certain periods when they had very little to do. He commended the suggestion to the First Lord that where possible naval medical officers should be allowed to attend on the wives and children of the men.

Sir D. MACLEAN said that the Vote as it stood was really incomprehensible, and he suggested that it should be withdrawn.

Sir J. CRAIG: No. Sir J. Craig said he would have the matter set right in the White Paper which he proposed to have prepared before the Report stage.

Dr. M'DONALD much regretted to find opposition to grant the necessary amount towards the expenditure on the medical services of the navy. Very frequently they had found in the past that the medical services in this country were utilised to a very large extent for the benefit of the nation more than for the benefit of the medical profession. He was sorry to hear the suggestion that naval medical officers should be asked to attend the families and children of the members of the Service. It had been suggested that many medical men were very often found with insufficient work. He had known some officers in the navy who had a considerable amount of time at their disposal as well as medical men. As to the increase of cost, many honourable Members did not realise the enormous increase in the cost of medicine and surgical appliances.

Mr. ACLAND said when he was Financial Secretary to the War Office he found there was no department in which it was more difficult to reduce expenses than the medical and nursing department. The Vote was agreed to.

TUESDAY, MAY 18TH.

Effect of the War on European Populations.

Mr. ALLEN PARKINSON asked the Under Secretary for Foreign Affairs whether he could issue a White Paper showing the best available information as to the effect of the war upon the populations of the various European countries, particularly the number of war casualties and other deaths and the decline in the number of births.—Mr. HARMSWORTH replied: I understand from the authorities in this country who study these matters that there is not yet sufficient information available to render it possible to contemplate the issue of a White Paper on the subject. A series of publications have, I believe, been prepared by a Danish writer, Mr C Doring, and copies have been obtained by the Royal Statistical Society, who would, doubtless, be pleased to permit the honourable Member to consult them on application

Exports of Morphia

SIR R HORNE (President of the Board of Trade) circulated the following statement of the recorded exports of morphia, which, he regretted, did not include exports through the post, particulars of which are not available:—

Statement showing the Quantity and Value of "Morphia and Morphia Salts, the Manufacture of the United Kingdom Exported from the United Kingdom to Each Country of Destination During the Year Ended Dec 31st, 1919 (Exclusive of Exports by Post)

Countries of destination	Quantity, ounces	Value, £	Countries of destination	Quantity, ounces	Value, £

Improved Conditions of School Children

MR HURD asked the President of the Board of Trade if he would cause to be collated and issued at the earliest possible moment for the information of the public the evidence upon which he based his statement that the children in public schools were better fed and better clothed than in the years before the war, that there were fewer free meals needed for badly nourished children than ever before, and that in these respects, as in that of unemployment, a marked improvement had taken place in the general condition of the wage earning community —SIR R HORNE replied· As regards the feeding of school children, the most recent report of the chief medical officer of the Board of Education published in 1919 gives on p 175 a table which shows that for the year 1918-19 the number of school children fed by local education authorities under the provisions of the Education (Provision of Meals) Act, 1906, was 52,490, as compared with 156,531 in 1913-14 and 358,306 in 1912-13 As regards improvement in the clothing of school children, there is no published information for the country as a whole, but I would refer to the statement made by the school medical officer for London on p 13 of the report to which I have referred, in which he says that in 1918 the number of children found insufficiently clad was less than half the number discovered in 1913 I understand that the general impression gained by the inspectors of the Board of Education has been that a similar improvement was to be found in other parts of the country As to unemployment there is less at the present time than in an average pre war year The percentage of trade union members reported as unemployed in January, February, and March, 1920 were 2 9 per cent, 1 6 per cent, and 1 1 per cent respectively In 1919 the mean annual trade union percentage of unemployed was 2·4 per cent, whilst during the last 40 years (excluding the war period) the mean annual percentage has only once fallen as low as 2 per cent, and on only four other occasions was it lower than 2 5 per cent —MR HURD Will the right honourable gentleman say when we can have information for later years? —SIR R HORNE I have given the latest figures with regard to unemployment With regard to the feeding of school children I have not the exact figures, but I am informed that what the school inspectors have to say on the subject bears out what is said in the report of 1918

WEDNESDAY, MAY 19TH

Opium Cultivation in India

MR GILBERT asked the Secretary for India if he would state the acreage under opium cultivation in India for each year from 1914 to 1919, the amount and value of opium produced in and exported from India in each year from 1914 to 1919, which were the countries this exported opium was consigned to, and the amount and volume of opium consigned to each country, respectively —MR MONTAGU circulated the following statements (A and B) —

(A) *Statement showing the Area under Poppy (in Acres) and the Outturn therefrom (in Maunds of 82⁴⁄₇ lb) in British India, 1913 14 to 1916 17*

Year	Area under poppy (acres)	Outturn in Maunds (1 Maund = 82⁴⁄₇ lb)
1913 14	144,561	24 292
1914–15	164 911	28 293
1915 16	167 155	27 001
1916 17	204,186	32 124

(B) *Statement showing the Quantity (in Chests), and Value (in Rupees) of Opium Exported from India 1913–14 to 1918–19*

Increases of Pay in Indian Medical Service.

Mr. Montagu (Secretary for India) informed Mr. Lunn that the approximate cost per annum of the recent increases of pay sanctioned for the Indian Medical Service was £250,000.

Medical Officers in Southern and Northern Nigeria.

Earl Winterton asked the Under Secretary for the Colonies if he would state what steps were being taken to deal with the serious shortage of medical officers in the service of the Southern and Northern Nigerian governors.—Colonel Wilson replied: Steps are being taken to revise the salaries of officers of the West African Medical Staff, and when the new salaries are settled they will be brought to the notice of possible candidates, but there is a great dearth of medical men at the present time.—Earl Winterton: Can my honourable and gallant friend inform the House what steps are being taken at the present time to deal with the situation out there? Is he aware that officials are dying for want of medical care?—Colonel Wilson: I am informed that the position is well known to the Colonial Office. The new scale of salaries will be issued very shortly now.

Dental Mechanics.

Sir Thomas Bramsdon asked the Financial Secretary to the War Office whether he was aware that the naval authorities employed unenlisted dental mechanics at trade rates; and was he prepared to employ discharged soldiers, dental mechanics, at trade rates in order to obviate the necessity of these men drawing unemployment pay, and thereby to do for them what the Government was urging private firms to do for discharged soldiers.—Sir A. Williamson (Financial Secretary to the War Office) replied: The military commands at home have been authorised to employ civilian dental mechanics at local rates where the services of such are necessary and where no enlisted dental mechanics of the Royal Army Medical Corps are available.

Sir Thomas Bramsdon asked the Financial Secretary to the War Office whether, in view of the number of unemployed discharged soldiers who were dental mechanics, it was necessary to inaugurate a costly scheme of training for this purpose.—Sir A. Williamson replied: In spite of special efforts which have been made to recruit dental mechanics, the numbers that have come forward are inadequate to meet the needs of the army. The course of training for recruits which has been instituted is carried out at the dental workshops already in existence, and there is no intention of inaugurating a costly scheme.

Compensation for Poor-law Officers.

Dr. Addison informed Mr. Briant that the Bill which he proposed to introduce for the reform of the Poor-law would contain provisions dealing with the compensation of Poor-law officers.

Medical Boards at Manchester.

Major Nall asked the Minister of Pensions whether he was aware of the increasing delays in arranging medical boards arising from the regional headquarters, Manchester, and that in consequence a large number of distressing cases were accumulating; and what steps he was taking to adjust the inconvenience and hardship thereby caused.—Major Tryon replied: My right honourable friend is not aware that there is general delay such as is referred to in the first part of the question; but if the honourable Member can supply instances of delay in particular cases I shall be glad to make inquiries. As regards the latter part of the question where the circumstances are such that a medical examination cannot be arranged in time to prevent an interruption in the award, arrangements are made to continue for a short period the expiring pension.

Thursday, May 20th.

Venereal Disease Statistics.

Captain Elliot asked the Secretary for War whether he could give the case-rate per 1000 of venereal disease amongst the British army in the United Kingdom, France and Flanders, and Germany (occupied territory) in the years 1918, 1919, and the first quarter of 1920.—Mr. Churchill replied: The approximate rates per 1000 of admissions for venereal disease are as follows:—

	Ratio per 1000 per annum.		Ratio per 1000 first quarter.
	1918.	1919.	1920.
United Kingdom	43	59	14·8
France	32	67	40·5
Army of the Rhine	—	46	42·3

The ratios for 1919 and 1920 are to a large extent fallacious owing to rapid demobilisation. There has been a rise in the incidence of venereal disease amongst the troops in France and Germany, but I am glad to say that the latest information shows some improvement.

Soldiers' Artificial Limbs.

Major Cohen asked the Minister of Pensions if he would state how many limbless soldiers had already been provided with their second artificial limb; and how many such soldiers were still waiting for the said limb; and whether it was his intention to provide boots free of charge in perpetuity to fit the artificial limbs of legless soldiers.—Major Tryon replied: It was not found possible to commence the supply of duplicate artificial limbs until last October, when the supply of first limbs had been practically completed, but on April 16th 5213 limbless soldiers had been supplied with duplicate limbs. There are in all about 32,000 men not provided with duplicate limbs, but not the whole of this number can be stated to be "waiting." The large majority of men are in employment, and will only attend fitting centres at a time convenient to themselves. Moreover, in a large majority of short stump-arm cases the men prefer not to wear an artificial limb; and there are cases of recent amputation not yet ready for fitting. Unless there is special urgency, cases are dealt with in rotation according to the date of supply of the first limb. As the artificial legs supplied by the Ministry are so made that an ordinary boot can comfortably be worn, I am not clear that there is any reason why boots should be supplied at the public cost.

Pensioners and Institutional Treatment.

Mr. Kiley asked the Minister of Pensions whether, in the case of ex-soldiers suffering from nerve strain who were considered to require institutional treatment, any part of their pension went to the institution providing the treatment; if so, how much; and, if the patient refused treatment, would any portion of the pension be forfeited.—Major Tryon replied: The answer to the first part of the question is in the negative. The charges made by the institution are defrayed by the Ministry. I may, however, explain that a discharged soldier under institutional treatment does not draw pension, but is maintained free of charge and receives allowances which are generally at the rate of 21*s.* per week with additions for rank and dependents. As regards the second part of the question, pension may be reduced by one-half or less if treatment certified to be necessary in the man's interests is unreasonably refused. Every case is considered on its individual merits.

Government Publications on the Use of Alcohol.

Captain Bowyer asked Mr. Chancellor of the Exchequer whether his attention had been called to an official-paid circular issued by His Majesty's Stationery Office, with an order form attached, relating to a publication entitled Alcohol: its Action on the Human Organism, issued by the Central Control Board (Liquor Traffic) under the chairmanship of Lord d'Abernon; why this publication was advertised at the public expense; whether he could point to any other official publications with regard to which similar methods of advertisement had been adopted; and would he state the number of these circulars that had been sent out.—Mr. Baldwin (Secretary to the Treasury) replied: My attention has been called to the circular to which my honourable and gallant friend refers. The publication in question is advertised at the public expense because it is a Government publication; and the method of advertisement used in this and other similar instances to which I could refer has been adopted as being in certain cases the most effective means of calling public attention to official publications. In this case about 40,000 circulars were sent out to all British medical practitioners, the total cost for the printing, address, and dispatch of the circulars amounting to about £60. The receipts already exceed this sum.

The late Dr. S. R. Savage, of Pretoria.—Dr. Savage died at Pretoria on April 27th. Born at Welteroreden, Rondebosch, a suburb of Cape Town, the deceased was educated at the Diocesan College, Rondebosch, at the Cape University, where he took his degree of arts, and subsequently qualified M.B., C.M. Edinburgh in 1886. On returning to South Africa Dr. Savage was for a time principal medical officer at Maseru, Basutoland, and later went into partnership with Dr. Clarke, of Bloemfontein. At the conclusion of the Boer War Dr. Savage went to Pretoria at Lord Kitchener's special request. Later he was appointed railway medical officer, and held this post until his death, in addition to a successful general practice at Pretoria, where he was accounted an obstetrician of special skill and merit. Dr. Savage was senior visiting physician to Pretoria Hospital and a member of the Asylum Board and of the Victoria Cottage Hospital Committee. At one time he was president of the Pretoria Branch of the British Medical Association. His publications include articles on Intra-orbital Periostitis and on Leprosy in British Basutoland in the *Cape Medical Journal* in 1893 and 1895 respectively. Dr. Savage gave his services generously to the community. He was a member of the first town board of Pretoria, subsequently a town councillor, and in 1908 he was mayor of the capital. He was one of the earliest presidents of the Victoria Cross Lodge of the Order of the Sons of England and a member of the Transvaal Lodge of Freemasons. Dr. Savage married a daughter of the late Bishop Bousfield and is survived by his widow and a large family.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication*

DENT, PATRICIA, M B , B S Lond , has been appointed Assistant Medical Officer for Maternity and Child Welfare and Assistant to the School Medical Officer for the County Borough of Wolverhampton

RIGBY, R A C, L R C P & S Edin , Honorary Medical Officer in charge of the X ray and Electro Therapeutic Department at the General Hospital, Nottingham

RYLAND, A, F R C S Edin , Oto-Laryngologist to the Whipps Cross Infirmary, Leytonstone

Certifying Surgeons under the Factory and Workshop Acts **DONALD, D A**, M B , Ch B Edin (North Berwick), **CHRISTIE, J C** M B , Ch B Glasg (Tarbert), **GARDINER, D G**, M B , Ch B Glasg (Stonehaven), **WARD SMITH, W**, M D Edin (Shipley)

Vacancies.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.
THURSDAY, June 3rd.—4.30 P.M., Bakerian Lecture: Sir Ernest Rutherford: The Nuclear Constitution of the Atom.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, May 31st.

ODONTOLOGY (Hon. Secretaries—G. Paton Pollitt, W. Kelsey Fry, J. Howard Mummery): at 8 P.M.
Annual General Meeting—Election of Officers and Council for 1920–1921.
Casual Communications by—
Mr. J. G. Turner, Mr. J. Harborow, Mr. Watson Turner, Mr. Pitman.
Paper:
Mr. Charles A. Clark: Relation of Teeth to the Floor of the Antrum (illustrated by radiographs and lantern slides).
Members of other Sections are invited to attend.

Tuesday, June 1st.

PSYCHIATRY (Hon. Secretaries—Bernard Hart, G. F. Barham): at 8.30 P.M.
Annual General Meeting—Election of Officers and Council for 1920–1921.
Paper:
Dr. David Forsyth: Psycho-analysis of a Case of Early Paranoid Dementia.

Thursday, June 3rd.

OBSTETRICS AND GYNÆCOLOGY (Hon. Secretaries—J. S. Fairbairn, Herbert Williamson): at 8 P.M.
Short Communications:
Dr. Philip Turner: Traumatic Rupture of the Pedicle of a Sub-peritoneal Fibroid.
Dr. Ford Anderson: A Case of Rupture of the Uterus.
Dr. Fletcher Shaw and Dr. Burrows: Radical Cure of Advanced Carcinoma of the Cervix made possible by the Application of Radium.
Specimen:
Dr. A. W. Bourne: A Specimen of Spontaneous Rupture of the Uterus Due to the Use of Pituitrin.
Paper:
Mr. Gordon Ley: The Pathology of Accidental Hæmorrhage.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, May 31st.—12.15 P.M., Dr. Burnford: Pathological Demonstration. 5 P.M., Mr. D. Armour: Subphrenic Abscess.
TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 5 P.M., Dr. R. J. Reece: Public Health.
WEDNESDAY.—2 P.M., Mr. Addison: Operations. 5 P.M., Dr. Owen: Irregularities of the Pulse, their Clinical Significance.
THURSDAY.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 5 P.M., Mr. Baldwin: Practical Surgery.
FRIDAY.—2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 5 P.M., Mr. MacDonald: Senile Enlargement of Prostate.
SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon: Mr. Sinclair: Surgical Anatomy of the Abdomen.
Daily:—10 A.M., Ward Visits. 2 P.M., In-patient and Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, May 31st.—2.30 P.M., Mr. J. B. Banister: Gynæcological.
TUESDAY.—9.45 A.M., Lieut.-Col. R. H. Elliot: Selected Eye Cases and Operations. 2.15 P.M., Selected Cases:—Mr. N. Fleming: External Eye Diseases. 3.15 P.M., Dr. Drinkwater: Methods and Apparatus for Anæsthesia in Dental Operations. 4.30 P.M., Dr. C. E. Sundell; Disturbances of Sleep in Children.
WEDNESDAY.—2.30 P.M., Dr. W. J. Oliver: Dermatological.
THURSDAY.—2.30 P.M., Mr. N. Fleming: Eye Cases. Dr. J. Metcalfe: Radiology.
FRIDAY.—2.30 P.M., Dr. C. E. Sundell: Diseases of Children.
SATURDAY.—3 P.M., Mr. Carson: Selected Surgical Cases.
Daily:—2.30 P.M., Operations, Medical and Surgical Clinics, &c.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, May 31st.—2–3.30 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Mr. Paton: Visual Fields.
TUESDAY, June 1st.—2–3.30 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Dr. Risien Russell: Demonstration of Ward Cases.
WEDNESDAY, June 2nd.—2 P.M., Mr. Armour: Surgical Treatment of Tumours of the Spinal Cord. (II.) 3.15 P.M.
THURSDAY, June 3rd.—2–3.30 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.15 P.M., Dr. Greenfield: The Pathology of the Nerve Cell and Peripheral Nerves.
FRIDAY, June 4th.—2–3.30 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Hinds Howell: Demonstration of Ward Cases.
Fee for Post-Graduate Course £7 7*s*. C. M. HINDS HOWELL, Dean.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Special Post-Graduate Courses in Diseases of Children, illustrated by cases, specimens, and radiograms.
Mr. A. T. Pitts: The Pathology, Results, and Treatment of Dental Sepsis in Children (in the Out-patient Department)—
WEDNESDAY, June 2nd.—4 P.M., Lecture III., The Diagnosis and Treatment of Dental Sepsis.
Dr. R. Hutchison: Disorders of Digestion and Nutrition in Childhood (in the Museum)—
THURSDAY, June 3rd — 11 A.M. Lecture I., Infant Feeding.
Dr. T. Thompson: Diseases of the Central Nervous System in Children (in the Museum)—
THURSDAY, June 3rd.—9.15 A.M., Lecture I., Functional Disorders of Childhood.
Dr. D. N. Nabarro: Methods and Significance of Pathological Investigations (in the Pathological Laboratory)—
FRIDAY, June 4th.—5 P.M., Lecture I., Examination of Blood:—Enumeration: Blood Culture.
Mr. T. Higgins: Common Surgical Disorders of the Naso-pharynx and Annexa in Childhood (in the Museum)—
THURSDAY, June 3rd.—5.15 P.M., Lecture I., Introductory. Naso-pharyngeal Adenitis.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.
MONDAY, May 31st.—5.30 P.M., Post-Graduate Lecture:—Dr. R. Wells: The Electrocardiograph in Practical Medicine. (II.)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).
A Course of Post-Graduate Lectures on Syphilis is being given by various members of the staff of King's College Hospital during the present year.
FRIDAY, June 4th.—9.15 P.M., Dr. S. A. K. Wilson: Syphilis in the Nervous System. (I.)

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton, S.W.
MONDAY, May 31st.—2 P.M., Dr. Melville: X Ray Department.
TUESDAY.—2 P.M., Dr. D. Grant: Throat Department. 2.30 P.M., Demonstration:—Dr. Wingfield: Cases Illustrating Onset.
WEDNESDAY.—10.30 A.M., Dr. Punch: Demonstration of Museum Specimens. 2 P.M., Dr. Gosse: Cardiographic Department. 2.30 P.M., Demonstration:—Dr. Young: Cases Illustrating Onset.
THURSDAY.—10.30 A.M., Dr. Burrell: Artificial Pneumothorax. 2.30 P.M., Demonstration:—Dr. Hartley: Cases Suitable for Artificial Pneumothorax.
FRIDAY.—2 P.M., Dr. Melville: X Ray Department. 2.30 P.M., Demonstration:—Dr. Burrell: Cases Suitable for Artificial Pneumothorax.
SATURDAY.—1 P.M., Dr. Batty Shaw: Special Demonstration in the Out-patient Department.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.
Post-Graduate Course on Infant and Child Welfare.
TUESDAY, June 1st, AND THURSDAY.—10.30 A.M., Dr. E. Pritchard: *Practical Demonstrations on the Management and Feeding of Infants and Young Children*—I., Causes of Infant Mortality; II., How to Establish an Infant Welfare Centre and Conduct an Infant Consultation.

UNIVERSITY OF LONDON.
Advanced Lectures in Physiology to Students of the University and others interested in the subject.
A Course of Eight Lectures on Nutrition will be given at King's College for Women (Household and Social Science Department), Campden Hill-road, Kensington, W.
MONDAY, May 31st, AND TUESDAY.—5 P.M., Lectures VII. and VIII.:—Dr. E. Mellanby.
A Course of Eight Lectures on the Bio-Chemistry of Sterols will be given in the Physiological Laboratory of the University, South Kensington, S.W.
TUESDAY, June 1st.—5 P.M., Lecture III., Mr. J. A. Gardner.

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE POST-GRADUATE LECTURES, at the Sheffield Royal Hospital.
WEDNESDAY, June 2nd.—4 P.M., *Prof.* A. Hall: Diagnosis of Nervous Disease. (II.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.
TUESDAY, June 1st.—4.30 P.M., Lecture:—Dr. G. R. Murray: Examination of the Thyroid Gland and its Functions.

Notes, Short Comments, and Answers to Correspondents.

MEDICAL PROGRESS IN CHINA SINCE THE REPUBLIC.

BY WU LIEN TEH, M.A., M.D. CANTAB., LL.D.,
PHYSICIAN EXTRAORDINARY TO THE PRESIDENT OF CHINA.

IN spite of the disturbed state of the country since the establishment of the Republic in 1911, the progress of medical and sanitary science has been very marked and steady. This has shown itself in two ways: (1) the readiness with which both the Central Government and the provincial authorities have established and supported hospitals and institutions of a sanitary nature; and (2) the increased interest shown by the general public in Western medicine, home cleanliness, and matters bearing a hygienic value.

The Plague Prevention Service.

The new era in modern preventive medicine may be said to have commenced in 1911, when the Chinese Government and people noticed the great superiority of accurate scientific methods as compared with crude haphazard methods for the suppression of the pneumonic plague in Manchuria. On one hand, they saw a body of clean, earnest, and fearless young men, equipped with knowledge, microscopes, instruments, and disinfectants, and succeeding in their work of suppressing the epidemic; on the other, they encountered talkative, old-fashioned, uncertain men, whose one idea was to needle and drug the patients, and who, because they took no precautions against the disease, died as easily as the patients. One great result of this epidemic was the establishment of the North Manchurian Plague Prevention Service, which I had the honour to direct, consisting of hospitals at Harbin, Tsitsihar, Sansing, Newchwang, Taheiho, Manchouli, and Lahasusu. Harbin, being the commercial centre of North Manchuria and also the principal focus of infection in 1911, has the largest hospital, covering an area of six English acres and containing an up-to-date bacteriological laboratory capable of handling all sorts of bacteriological research. In ordinary times, when no epidemic exists, these hospitals are used for general purposes, surgical operations being performed and in-patients suffering from various ailments being admitted for treatment. The medical staff of the Plague Prevention Service consists of ten male and two female doctors, distributed among the different hospitals. Inside the hospital at Harbin there is a fine medical library, much patronised by the American and other foreign doctors of the city. An interesting museum of medical objects is also attached to it. Besides annual medical reports, the Plague Prevention Service has published two voluminous scientific reports containing research and other matters carried out by members of the Service. Now and then, as during the last summer, another epidemic than plague—namely, cholera—claimed the attention of the staff. Although very severe, it was suppressed within six weeks with the low mortality of 14 per cent., as compared with a mortality of 50-60 per cent. in other cities, where the outbreak did not subside until the end of November.

Interesting Medical Landmarks.

In November, 1913, a presidential mandate was issued authorising the dissection of dead bodies in China. This, together with the Imperial sanction of cremation of cadavers from plague in 1911, has undoubtedly paved the way further for medical progress in China. Another interesting landmark in the annals of medicine in this country was the foundation of the National Medical Association in 1914, when 30 medical graduates from European, American, Japanese, and Chinese colleges met together in Shanghai and formed the nucleus of the Association. It has now a membership of over 450 male and female members. The first President was Dr. Yen Fu Ching, M.D., of Harvard, and the second was myself. So far two conferences of the Association have been held, one in 1915 (Shanghai) and one in 1916 (Canton). The third one will be held this year in Peking in conjunction with the Medical Missionary Association, at which it is expected famous anatomists, physiologists, and specialists will attend from various parts of the world.

On Sept. 30th, 1915, an important mandate was issued recognising Western medicine as the proper standard of medical practice in China. Anyone practising medicine in the country will henceforth be required to produce a certificate from the police. It would be better if this power were centred in the hands of a recognised Central Medical Council, but until that comes into being the police permit will have to stay.

Up to 1915 Peking had no proper hospital for the treatment of infectious disease, such as scarlet fever, diphtheria, typhoid, &c. Thanks to the liberal policy of the then Minister of Interior (Mr. Chu Chi Chien) a hospital for this purpose was built in the Tenth-street, North City, capable of accommodating 60 beds. This hospital has done most creditable work under the combined direction of Yen Chi Chung (graduate of Tokio University) and Dr. S. P. Chen (M.B. of Cambridge). Cases of small-pox are now sent to an auxiliary epidemic hospital in the grounds of the Temple of Heaven outside Chien Men.

The year 1914 saw the visit to this country of a commission of medical experts appointed by the Rockefeller Foundation to consider the possibility of establishing two first-class medical colleges in China for the training of future Chinese doctors. Another commission followed in 1915, and as a result it was decided to found two well-equipped colleges and hospitals, one in Peking and the other in Shanghai. The one in Peking is now nearly completed, and will be formally opened in the fall of 1920. The cost of this place has approximated 5 million gold dollars, and it is expected that the annual budget will not be less than 1 million, though only 100 students will be trained at one time. When finished and in working order the Rockefeller Medical College and Hospital of Peking will eclipse anything in existence in Europe or Asia in the magnificence of its architecture and the completeness of its outfit.

The Peking Central Hospital, upon which the writer devoted the best part of four years in collecting funds, constructing, and equipping, was finally opened on Jan. 27th, 1918. The total cost is $300,000. It is modelled upon the American plan and possesses three storeys and a basement. It contains four large wards, each accommodating 25 beds, as well as a series of fine private rooms for first and second-class patients. Until the opening of the Rockefeller Hospital, the Central Hospital will stand as the finest institution of its kind in China or Japan.

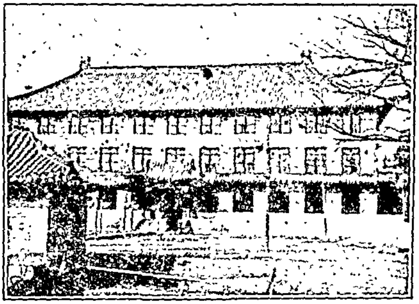

FIG. 1.—The New Rockefeller Hospital and Medical College in Peking: the Central Administrative Building.

As a result of the second visitation of pneumonic plague in China in 1918, the Central Government devoted the balance of the 1 million loan (obtained for the suppression of the epidemic) to the establishment of an institute for infectious diseases in the grounds of the Temple of Heaven, a beautiful spot covered with old pine trees. Here a series of isolated red-brick buildings have been erected for the different departments of the institute—e.g., investigation, serum, veterinary, chemical, &c. Over 40 experts, mostly graduates of Japan, are connected in one way or another with the institute. During the last summer, when cholera threatened Peking and the vicinity, this institute distributed vaccine made in its laboratories for use among the troops. The chemical department undertakes to analyse patent medicines and chemicals submitted to it for a fixed fee. The institute is connected with the Ministry of Interior, and comes directly under the Department of Sanitation.

The first medical college established in North China is Peiyang Medical College, now Naval Medical, founded in 1893 by Viceroy Li Hung Chang in honour of the services rendered to his family by the British missionary, Dr. Mackenzie. After Dr. Mackenzie's death several past students of the college were appointed directors, of whom the most prominent was Dr. W. T. Watt. The present staff consists of Dr. H. Y. King (director), four French, one British, and ten Chinese professors. The Army Medical College was started in Tientsin in 1903 by Viceroy Yuan Shi Kai, the first director being Dr. Hsu Hua Ching, one of the first four graduates of the Peiyang Medical College. In 1918 this college was transferred to Peking. As at present constituted, it occupies an enormous area in the East City between the Fifth and Tenth-streets, the ground comprising nearly 40 acres. Besides the college and hospital there will be built a veterinary college and a military drug factory. The whole place is under the efficient management of

Surgeon-General Chuan Shao Ching. The total cost is in the neighbourhood of $800,000.

Coöperation of Chinese and Foreigners.

A noteworthy feature of this medical progress is the increasing coöperation of Chinese and foreigners. Instead of adopting an exclusive policy, missionary institutions are inviting more and more the assistance of their Chinese colleagues. This liberal-mindedness is a wise one, for the natural teachers, healers, and research-workers in China are the Chinese themselves, many of whom have now received a first-class training abroad. In this respect the China Medical Board of the Rockefeller Foundation is more far-seeing than the authorities of the Hong-Kong University, for it has already on its staff at least 12 Chinese doctors out of a total of 33 teachers.

Other institutions which have contributed considerably to the progress of medicine in China are the Yale Medical School in Changsha (Hunan); the Union Medical Department of the Shantung Christian University (Tsinanfu); the Kung Yi Medical College and Hackett Medical College (both in Canton), where women receive a good training. The French Medical College in Canton, with which is affiliated the Hospital Doumer; the Sino-French Medical College at Changtehfu (Honan), to which is attached a small Institut Pasteur; and the Medical Department of the French Catholic University of Aurore in the French settlement of Shanghai.

One institution, unique in its way, has perhaps done more than any individual school for the propagation of hygienic ideas among the masses. This is the famous Tsinanfu Institute, founded in 1905 by the Rev. J. S. Whitewright, of the English Baptist Mission. The buildings cover over three English acres and have cost over $150,000. About half a million persons visit the institute in the course of one year. There should be at least one such institute in every large city in China for the training of the masses in modern progress, including hygiene.

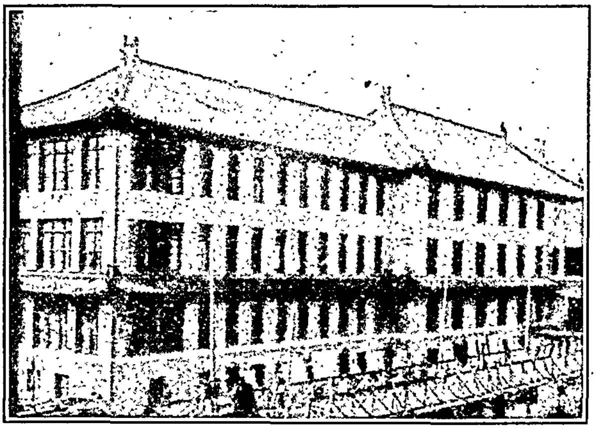

FIG. 2.—One of the General Wards where the sessions of the Joint Medical Conference of Feb. 21-28 were held.

An interesting advance has been made in the appointment of a Terminology Committee, consisting of representatives of the Ministry of Education, National Medical Association, Medical and Pharmaceutical Society, Medical Missionary Association, and Kiangsu Educational Association, to determine the terms to be used throughout China. So far, the complicated terms of anatomy have been finished and accepted by the Government as official. The terms in bacteriology, chemistry, and physics have also been finished and are awaiting recognition.

It is generally acknowledged that until the poorer classes practise hygiene as well as the educated classes, infectious and other communicating diseases will not be stamped out. Knowledge of simple laws of health are therefore essential among high and low. With a view to carrying out such work, the Joint Council of Public Health Education was formed in 1916, consisting of representatives from the Y.M.C.A., National Medical Association, and Medical Missionary Association, with offices at 5, Quinsan Gardens, Shanghai. The two secretaries are Dr. W. W. Peter and Dr. S. M. Woo. Their method of work consists in preparing travelling exhibits of automatic models, plans, lantern slides, "movies," and other methods by which the attention of the audience may be arrested and retained. Besides the above, hundreds of thousands of pamphlets snd booklets have been issued and sold at cost price. Among the titles of these books may be found: How to Live, First Aid in the Home, Sanitation of a Chinese City, Tuberculosis, Infant Hygiene, Plague, Small-Pox, Venereal Disease, Care of Teeth, Care of Eyes, Cholera, Sexual Hygiene for Young Men, &c. These books have had an enormous sale, showing that the public are interested in promoting hygiene.

Pressing Needs in the Medical Line.

Acting on the principle that "Discontent is the Essence of Progress," I am still far from satisfied with the speed at which sanitary matters have been undertaken by the authorities. The public health of the country should be invested in the hands of a business-like Central Health Bureau, with power to control epidemic diseases, collect and distribute vital statistics, manufacture vaccines, and perform analyses. In addition, a Central Medical Council should be established in Peking, consisting of leading medical men as well as representatives of the Government, for the control and supervision of medical education and practice. The time has come when the old-style methods of practice should be absorbed into the modern methods, or else prohibited entirely in a limited number of years. The present system of simultaneously employing native-trained and Western-trained medical officers in Government hospitals and in the army is wasteful and backward. Hygiene should be more widely taught in elementary and high schools, and properly trained school doctors employed to supervise the health of the pupils, so that all the defects may be at once discovered and corrected instead of being allowed to undermine the health and often shorten the lives of the children. The supervision of public health should be in the hands of proper sanitary boards, comprising leading physicians and business men, as well as the police authorities. Social leagues should be founded wherever possible by leading citizens, men and women, and future mothers taught practical details for the management of a healthy home and family. The present tendency among the people, especially women, to buy patent medicines for headaches, constipation, menstrual pain, backache, sleepnessness, and even sterility is widespread, and can only be stopped by a fuller understanding of the laws of nature and a higher conception of the ethics of the medical profession. It may be further promoted by access to such public institutions as natural history museums, public health exhibits, industrial museums, commercial and technical displays throughout every large city in the land. As the trade of the country expands and technical and commercial education becomes more popular these institutions will, no doubt, be established.

REMOVAL FROM THE PANEL: THE TRIBUNAL UNDER THE NATIONAL INSURANCE ACTS.

THE recent discussion in the House of Commons upon the legal position of the practitioner threatened with removal of his name from the panel (THE LANCET, May 22nd, p. 1139) suggests that the procedure adopted is not very widely known. We therefore print, with substitution of the actual names, a typical correspondence on the subject.

Ministry of Health, 19th May, 1920.

Barchester Insurance Committee and Dr. A.B.C.

SIR,—I am directed by the Minister of Health to enclose a copy of the report made by the Inquiry Committee appointed to consider the representations made by your clients, the Barchester Insurance Committee, against Dr. A.B.C., and to state that, in view of the findings contained in the report, the Minister is not satisfied that the continuance of Dr. A.B.C. on the panel would be prejudicial to the efficiency of the medical service of insured persons, and he has accordingly decided to take no further action in the matter.

In view, however, of the breaches of the Medical Certification Rules disclosed in the report, the Minister would have been disposed to inflict a monetary penalty on Dr. A.B.C. by means of withholding Exchequer grant from the Committee, had the Committee recommended this action in the first instance; and for this reason he does not propose to make an order with regard to the costs of the inquiry,

I am, Sir, your obedient servant,
(*Signed*) R. H. CROOKE.

The Solicitor to Barchester Insurance Committee.

THE PSYCHOGENIC TREATMENT OF APOPLEXY.

A CORRESPONDENT has sent us a cutting from the *Medical Times* for May, in which Dr. Eli Grellet Jones, who is described as president of the "Medical Society of the United States," contributes an original communication on the Treatment of the After-effects of a "Stroke of Apoplexy." Dr. Jones, who is a graduate of Dartmouth Medical School, Hanover, N.H., has found that "kali mur., third decimal trituration" is the remedy upon which we can depend to prevent inflammatory deposits about the apoplectic focus. It not only helps to absorb exudates, but also helps to cure the hemiplegia. A heartfelt "God bless you, Doctor," from many old people whose lives he has thus prolonged, has comforted him greatly for his labours in this field. It will, we think, long be the duty of the general practitioner to make his patient's life as happy and comfortable as may be by psychogenic means in many incurable morbid conditions, especially by showing him how to live within the limits of his disabilities. Dr. Jones evidently carries out psychogenic treatment of this sort with satisfaction both to himself and to his patients, but we do not think he is, in so doing, making an original contribution to medical science, nor can we find in the *American Medical Directory* any reference to the society over which he is stated to preside.

Goulstonian Lectures

ON

THE PRINCIPLES OF MEDICAL SCIENCE AS APPLIED TO MILITARY AVIATION

Delivered before the Royal College of Physicians of London

BY J L BIRLEY, C B E, M B, B CH OXON, F R C P LOND

LECTURE II *—WAR FLYING AT HIGH ALTITUDES

Delivered on March 11th 1920

IN the last lecture I had occasion to refer to exposure to high altitudes as a factor in shortening the flying officer's period of efficiency and accelerating the onset of fatigue To day I propose to consider the very difficult and important question of altitude in detail, fully realising that it entails a journey into the sphere of pure physiology and a consideration of highly technical data, to express my own opinion on which would certainly savour of presumption I shall, therefore, attempt first to present the actual facts as observed, and, secondly, to discuss, and if possible interpret, them on as broad a basis as possible And here it is as well to realise that the great development of the powers of the aeroplane has provided a remarkable example of the value of what is sometimes termed "academic" research—that is to say, of investigations which at the time they are made appear to have little applicability to the problems of the present, or even of the immediate future It was, in fact, exactly 40 years before flying at high altitudes became practicable that the physiological principles involved had been definitely established by the masterly researches of Paul Bert[1]

THE GROWTH OF FLYING

It was not until the closing months of 1916 that our thoughts were directed towards the subject of this lecture At that time, however, a machine made its appearance in the field which was capable of reaching an altitude of nearly 20,000 ft I well remember hastening down to the aerodrome where this new prodigy was on view and interviewing an extremely small person whose diminutive stature and boyish demeanour belied his proud claim to having attained military age He had only a few minutes previously landed from an altitude of 18,000 ft, where he had been engaged in the novel experience of testing his marksmanship on an enemy balloon which had drifted many miles over our lines The fact that he had not succeeded in hitting this enormous target failed both to depress him and to impress me Except for admitting that he had felt "lonely and cold up there," he protested complete ignorance of any untoward symptoms, and appeared refreshed rather than fatigued by his experience Shortly afterwards, however, I had occasion to visit a squadron where I found a very different state of affairs This unit had been employed for the past two months on patrols at 15,000 to 17 000 ft, and the effects of altitude had become, unprompted from any medical source, a subject for discussion in the mess All the pilots were agreed that the work was very fatiguing, and except for a certain degree of dyspnœa in the air the chief effects were felt after landing the most usual symptom being frontal headache

It was therefore clear that a new problem had arisen which the science of medicine would have to help to solve To what extent matters in this direction would develop was a matter of conjecture, but that it would necessarily be limited was early apparent, since the internal combustion engine was likely to suffer as much from oxygen want as the occupant of the machine which it propelled

THE MILITARY ASPECTS OF HEIGHT

Apart from its adverse effects on the human organism superiority in altitude confers definite tactical advantages It enables the pilot to get beyond the reach of his opponent, and in this happy and secure position to reconnoitre at his leisure, or to reach the objective to be bombed, and to return with a minimum of interference from the enemy During the war the advantage for reconnaissance was definitely realised, that for bombing, however, only imperfectly The latter was clearly sought after by the enemy in his raids on England, since all the later machines employed for this purpose were equipped with oxygen apparatus But the most important advantage which altitude conferred was undoubtedly that connected with fighting in the air An aerial combat between modern scout machines is, as a rule, a matter of seconds rather than minutes and the advantage of initial speed in attack is inestimable Superiority in height confers this advantage by enabling the pilot to dive on his opponent It was for this reason that it seemed essential for fighting machines to be capable of attaining great and still greater altitudes without at the same time losing so much engine power as to render them unairworthy and devoid of manœuvrability

These mechanical considerations were profoundly modified in practice, since the purely mechanical advantages of height were in great measure counterbalanced by its physiological disadvantages I think I should be fairly correct in stating that in 1918 all purely fighting machines had a "ceiling" of at least 20,000 ft, and equally correct in estimating the decisive combats at this altitude at less than 1 per cent, and those above 15,000 ft at less than 20 per cent, of all that took place This discrepancy was not due to the fact that machines did not fly at the higher altitudes, but was largely although not entirely, attributable to a great many factors of a purely military nature which cannot be discussed here Fighting pilots, in fact, came to look upon the advantage of altitude as one not to be lightly thrown away, but, at the same time as one which under certain circumstances might be dispensed with The decision as to which course to pursue rested largely with the fighting qualities of the machine, and where a pilot was confident of superiority in this respect he was often prepared to discard the dubious advantages of height Towards the end of the war the physiological effects of great altitudes became so widely recognised that in one part of the line pilots were instructed not to fly above 16,000 ft This order could not be enforced and was, in fact, disobeyed for the simple reason that they preferred the obvious tactical advantage to what seemed to many the purely hypothetical drawbacks, and the instinct of self preservation guided their conduct It has always been my opinion that the paralysing and insidious effects of oxygen want had a far greater influence in determining the course of aerial operations than has yet been realised

HIGH ALTITUDES BEFORE THE ADVENT OF THE AEROPLANE

Our knowledge regarding the effects of high altitudes no doubt originated in the experiences of mountaineers nevertheless, experimental balloon ascents[2] date back as far as 1800

In 1800 Robertson and a companion ascended from Hamburg to 21 500 ft and observed pain in the ears and difficulty in hearing one another speak In the same year Gay Lussac and Biot ascended from Paris to 23 000 ft and noticed in addition to the great cold laboured breathing quickened pulse and headache In Italy also in 1800 Zambecari Grassati and Andreoli made a similar ascent, all were nearly frozen to death, and the two former became unconscious In 1831 Glaisher and Coxwell made their historic ascent At 19 000 ft cyanosis rapid pulse and difficulty in breathing were recorded together with difficulty in reading instruments although they could be seen perfectly well at greater altitudes great muscular weakness supervened and at 29 000 ft Glaisher fell down unconscious, Coxwell however although paralysed in his limbs was able to open the valve by pulling on the valve cord with his teeth The lives of both men were saved and it certainly appears a little remarkable that shortly after landing they were able to walk home a distance of some seven miles In 1875

---

* Lecture I was published in THE LANCET of May 29th (p 1147)

Tissandier, Sivel, and Croce-Spinelli, under the direction of Paul Bert, made their famous but fatal ascent to 27,500 ft., to which further reference will be made.

Just previous to the war the Pike's Peak expedition[3] had published its report on the physiological effects observed during the first few days after reaching the summit (14,100 ft.) and during the subsequent processes of acclimatisation and deacclimatisation, while in 1912 there appeared an account of the Duke of the Abruzzi's remarkable expedition to the Himalayas made three years previously.[4] The main conclusions of these two expeditions were in direct opposition to each other. Whereas "mountain sickness" was experienced by all four members on arrival (by *train*) at the summit of Pike's Peak, and shortness of breath and undue fatigue on exertion were experienced even when "acclimatised" by a stay of five weeks on the mountain, four members of the Abruzzi expedition made an ascent from 22,842 to 24,600 ft. through deep soft snow "without exhaustion, without lowering of morale, without exaggerated difficulty of breathing, without palpitation or irregularity of pulse, and with no symptoms of headache, nausea, or the like." And the report goes on to add, "the fact of the immunity admits of but one interpretation—namely, that rarefaction of the air under ordinary conditions of the high mountains, to the limits reached by man at the present day, does not produce mountain sickness."

The experiences of the Abruzzi expedition were at variance with early experiences in the air in France, and it was obvious that whereas in the former a high degree of acclimatisation had had time to develop, a similar compensation was denied to the aviator. In other words, an individual sitting quietly in his machine might fly without discomfort to 16,000 ft., but if he had landed on a mountain aerodrome at this height he would almost certainly have been incapable of walking 100 yards.

The experiments made several years ago by Haldane and his collaborators, both in steel chambers and by breathing air deficient in oxygen, were chiefly of theoretical interest. The majority of them, moreover, were of short duration, and the subjects were few in number. They had nevertheless demonstrated a fact of the greatest practical importance and interest—viz., the existence of wide individual variations in response to oxygen-want.

MEDICAL ASPECTS OF HIGH FLYING AS OBSERVED DURING THE WAR.

A. *Effects while in the Air.*

Up to about 15,000 ft. a great many individuals noticed nothing unusual provided the flight was a short one, while a smaller number were similarly unaffected in short flights at considerably greater altitudes. The speed of ascent was an influence difficult to estimate; much more important was the duration of exposure to great altitudes. Remaining at anything over 15,000 ft. for over an hour was nearly always productive of some noticeable alteration, which was aggravated by increase of altitude and length of exposure.

1. *Mental effects.*—These corresponded in every way with what has been observed in other conditions when the organism is suffering from want of oxygen, accidental (carbon monoxide poisoning) and experimental, and consisted of a dulling of perception rather than of sensation.[5] Memory was similarly affected and the registration of events incomplete. Many an officer has been taken to task for lack of observance on high reconnaissance owing to his inability on landing to report what he had observed, and squadron commanders were eventually in the habit of drawing up a pro forma report with a questionnaire necessitating nothing more than a filling in of yes or no. One squadron commander informed me that not only did this help him to get accurate information, but that if his officers were left to write out their reports in full "they would be muddling about at them for hours," and make so many mistakes in writing and spelling as to render them barely decipherable.

Officers doing long reconnaissance, although able to see the ground perfectly, often failed to recognise the country they were flying over, while some amusing incidents were provided by observers making mistakes with their cameras; they were usually aware that something was wrong, but indignantly attributed the mischief to some fault of the camera rather than to their own mental incapacity. One observer returned from a high photographic reconnaissance well pleased with his effort until it was discovered that he had taken 18 photographs on the same plate; when tested in hospital by the nitrogen-diluting method to 18,000 ft. he fell fast asleep, and could only with difficulty be roused.

The onset of these mental effects was so insidious as frequently to pass unnoticed. In character they are not at all unlike those produced by alcohol. Pilots have attacked enemy formations without any plan of campaign but from sheer bravado, making tactical errors of which under ordinary circumstances they would never have been guilty; on the other hand, an officer has been known to wave his hand in friendly greeting to the enemy. Irritability and unreasonableness were other characteristic features; in a certain type of machine in which pilot and observer communicated with one another by means of hastily written notes one pilot threw all the notes overboard without reading them in sheer disgust.

Diminution of auditory sensations was generally recognised, but the fact that the engine became almost inaudible above 20,000 ft. never seemed to strike them as remarkable.

Another feature was the tendency to go to sleep. A pilot, for example, was returning from a long bomb raid at 17,000 ft. using oxygen; as he did not begin to descend after crossing the lines, but appeared intent on gaining the English coast rather than his own aerodrome, his observer reluctantly took action and roused him from his sleep, which was due to his oxygen-supply having run out.

The mental effects of oxygen-want have never been more vividly described than by Tissandier, the sole survivor of the balloon ascent in 1875, in which all three individuals were provided with oxygen but were paralysed before realising the necessity of using it. "The condition of torpor which overcomes one is extraordinary. Body and mind become feeble little by little, gradually and insensibly. There is no suffering; on the contrary, one feels an inward joy. There is no thought of the dangerous position; one rises and is glad to be rising. The giddiness of high altitude is not an empty word; but so far as I can judge from my own impressions it appears at the last moment and immediately precedes extinction, sudden, unexpected, and irresistible."[1]

Although the mental effects at altitudes commonly reached during the war (15,000 to 23,000 ft.) so often passed unnoticed, many experienced officers fully realised the characteristic impairment of judgment, the delay in making up one's mind, or even a complete inability to do so. From the military standpoint two effects are of particular importance. The first is what may be described as a loss of morale, which was recognised by many officers; the offensive spirit dwindles to nothing and there is a general disinclination to do anything more than wait about until it is time to fly home. The second is the inaccuracy and lethargy of the mental faculties, rendering rapid action impossible; this is reflected in the statement of many that they shot badly at great altitudes. A great deal remains to be done in the investigation of the alteration in psychometric reactions in anoxæmia before we can elucidate the problems of aerial warfare. Nevertheless, these considerations would seem to go far to explain the comparative rarity of aerial combats above 16,000 ft.

2. *Alterations in breathing.*—Nose-breathing ceases at about 12,000 ft. in most people, while at higher altitudes deeper breathing becomes noticeable. To remain at, say, 17,000 ft. or more for any length of time causes definite hyperpnœa, usually described as "difficulty in getting one's breath." The periodic type of breathing was apparently less common, but nevertheless occurred. One pilot, for example, during a test flight, in which he attained 18,500 ft. in about 20 minutes, was so overcome and periodic breathing became so severe that he lost control of his machine; he managed to get down and land safely, but had to be helped out in a dazed condition and was unable to walk without support. When tested in hospital up to 18,000 ft. periodic respiration began early and persisted for 20 minutes after the termination of the experiment.

The power of holding the breath, although, of course, not noticed by the flying officer, is greatly diminished at increasing altitudes; in fact, I was in the habit of using this test as a rough indication of the efficacy of oxygen apparatus.[6] This is shown in Tables I. and II.:—

EXPERIMENT I.—*Without Oxygen.*			EXPERIMENT II.—*With Oxygen.*		
Time from start in minutes.	Height in feet.	Time breath held in seconds.	Time from start in minutes.	Height in feet.	Time breath held in seconds.
0	Ground	82	0	Ground	78
14	10,000	71	9	3,000	78
29	15,000	53	18	8,000	81
46	18,000	32	35	12,000	75
68	20,000	24	48	14,500	79
87	20,850	13	56	16,000	74
121	8,000	57	67	16,500	75

Respiratory symptoms were naturally aggravated by exertion—e.g., fighting, using a pressure pump, taking photographs, talking, &c.—and under these circumstances were observed at comparatively low altitudes—e.g., 14,000 ft.

3. *Muscular weakness.*—This affected observers rather than pilots. The slightest exertion, such as bending down and drawing the shutter of the camera, or even talking, was "hard work." An observer's activities when fighting, standing up, operating a machine gun, and swinging a

heavy mounting were very considerable, involving an amount of work which doubled or trebled the respiratory per minute volume Under these conditions they rapidly became breathless and exhausted, and engagements had to be broken off

Nearly all pilots agreed that machines were difficult to fly at great altitudes, owing, as they supposed, to "the thinness of the air" That this was to some extent due to muscular weakness seems proved by the fact that when supplied with oxygen the difficulty largely disappeared

4 *Fainting* —The only certain instances of this occurred amongst observers after exertion

5 *Vomiting and hæmorrhage* —The former was very rare, and only one case of the latter (epistaxis) was reported

6 *Frequency of micturition* —This phenomenon was very common, and is probably explained by the combination of cold and vibration

B *Immediate After effects*

About the fatiguing effects of high altitude flying there was complete unanimity The scout pilot, it is true, was relatively little affected, but for those who were employed on long and high reconnaissance and patrols the after effects were actually distressing To realise this one only had to watch a flight landing from high patrol The gait is unsteady and laboured, reports are laboriously made out (there being a general disagreement as to what was seen and done), tempers are short, everybody looks and feels tired, and the idea uppermost in the mind is to lie down and go to sleep Severe frontal headache is common, it may persist until the following day and at times prove incapacitating Appetites are poor and spirits depressed It is easy to understand that a repetition of this kind of work over any length of time was rapidly productive of deterioration of mental and physical well being

The chief characteristics of flying at high altitudes were, therefore, an impairment of efficiency in the air and, as a result of its exhausting effects, a shortening of the active service period

This summary, however, requires qualification, for there was always a small but important minority of officers who were remarkably resistant to anoxæmia Scout pilots who were never subjected to long exposures especially denied any ill effects, either immediate or cumulative, and even officers employed on long reconnaissance occasionally showed unexpected powers of resistance An example of this may be mentioned —

Captain X, D S O, M C, age 21 Long distance runner since early boyhood 550 hours flying as instructor, 150 hours' active service, 1916, now completed another 300 hours' active service fighting reconnaissance at 18 000 to 21,000 ft Weight (estimated), 150 lb, height, 5 ft 9 in, breath holding, 110 seconds, expiratory force, 180 mm Hg, vital capacity, 4250 c cm, B P, 120 85, pulse sitting 80, standing 78, exercise 85 As a flight commander he has "set the pace" in his squadron, and has been entirely immune to the ill effects which were being experienced, largely as a result of his leadership, by his own observers and the rest of his companions Judging by results, he was clearly efficient under conditions in which the rest could barely manage to follow He saw at least two relays of officers go home exhausted after three or four months before he at last began to suffer from severe headache after landing, and a little later from symptoms in the air

THE USE OF OXYGEN IN AERIAL WARFARE

From experience which was accumulating in the field and from the results obtained by previous experimenters the necessity of equipping machines with oxygen apparatus was self evident At what altitudes oxygen would be necessary was less clear, although its use at comparatively low altitudes appeared desirable from the purely physiological standpoint

At this time (end of 1916) it seemed likely that oxygen would be more particularly required by the fighting scout owing to its great and increasing climbing powers Remembering that in the modern military machine a pilot frequently had as many as 20 instruments to watch, it seemed essential to provide him with an apparatus which would require no attention It accordingly had to deliver the requisite amount of gas automatically, and, in addition, had to be provided with a simple indicator so that a pilot could see at a glance whether his instrument was working satisfactorily That the amount of oxygen delivered should be regulated by the instrument and not by the pilot was further indicated by the consideration that the latter is no judge of when or in what quantities he requires oxygen, while his attention was likely to be diverted by the necessities of the moment from symptoms the significance of which he could not be expected to gauge Further, as every ounce of weight was supposed to make a difference to the performance of the scout machine, and as space was at a premium, the apparatus had to be light and compact

These desiderata were satisfied by the apparatus designed by my recent colleague, Professor Dreyer, on whose advice in these and many other matters I so largely and gladly relied The essential feature of this apparatus was the regulation of oxygen delivery by an aneroid controlled valve, so that the amount delivered varied in inverse proportion to the barometric pressure surrounding the instrument, and, consequently, in direct proportion to the height

The reasons for the unsuitability of any high pressure oxygen apparatus as opposed to liquid oxygen for use in aeroplanes in war time are of no physiological importance except that the weight and bulk of the cylinders limit the amount of oxygen which can be carried The military drawbacks cannot, however, be disregarded, but it is only *fair to remember that the industrial position of this country differed fundamentally from that of Germany The latter cut off from the nitrate supplies of South America was forced to develop on a large scale the manufacture of liquid air in order to secure the supplies of nitrogen necessary for* making explosives They therefore had no difficulty in equipping their aeroplanes with liquid air or oxygen

It is evident that the constant delivery of oxygen in suitable quantities, automatically controlled by changes in altitude, will keep the pilot under physiological conditions throughout his flight, and that accordingly continuous delivery is greatly preferable to an intermittent one, in which the quantities delivered would be largely controlled by the pilot Unfortunately, however, continuous delivery entails the constant wearing of a face mask, or at least (though far less satisfactory) of a pipe held between the teeth, and it was on this seemingly trivial point that the use of oxygen by the fighting scout pilot, for whose particular *benefit all our plans had been laid, broke down*

There is an old saying, I believe, that "no man ever commits suicide with his hat on" Certainly it proved to be the case that practically no pilot, whose prime duty it was to seek out the enemy and destroy him or be destroyed relished the prospect of undertaking *the task with a mask* over his mouth and nose *For much the same reason several of the most famous fighting pilots dispensed with their goggles and even their flying helmets* Whether this natural dislike, one can hardly call it prejudice, can be overcome by education remains for the future That it nevertheless is possible to fight, and fight successfully, with a mask was demonstrated by not a few officers who were attached when engaged on long and high reconnaissance, a type of work for which oxygen was absolutely essential We had unfortunately, a practical demonstration that long reconnaissance (three hours or more) at 20,000 ft was impossible without oxygen Not only were officers unable to give an account of their observations on landing, but the numbers available for duty rapidly dwindled To these individuals oxygen in spite of the mask came as an unmitigated blessing Ability to make full use of an aeroplane's climbing powers and performance at altitudes ranging up to 22 000 ft with conservation of the individual's well being enabled single machines without escort to make the most valuable and comprehensive reconnaissances far over the enemy's territory Two squadrons which were confined *to this kind of work*, in a few months took an enormous number of photographs over a large range of enemy country with comparatively light casualties, while the length of the active service period among their officers was at least as high as any other squadrons in the field

The Quantity of Oxygen Required

The amount of oxygen required to maintain physiological conditions naturally depends on (*a*) the altitude, and (*b*) the volume of air breathed per minute, which in turn depends on (*c*) the amount of work done The relation of barometric pressure to altitude is seen in Table III,[7] to which is added for convenience the percentage of oxygen in the inspired air which measured at sea level would give the same values of

TABLE III

Barometric pressure in Hg	Altitude in feet	Corresponding O_2 percentage at 760 mm	Barometric pressure in Hg	Altitude in feet	Corresponding O_2 percentage at 760 mm
760	0	20 96	412	16 000	11 37
704	2,000	19 38	382	18,000	10 56
651	4 000	17 93	354	20 000	9 78
602	6 000	16 60	328	22 000	9 06
557	8 000	15 37	303	24 000	8 35
516	10 000	14 25	278	26,000	7 68

444	14,000	12 28	230	30 000	6 40

partial pressure of oxygen as exist in ordinary air at the corresponding altitudes.

A pilot being more or less immobilised in his machine is debarred from taking exercise, while his somewhat cramped position probably handicaps deep breathing. His observer, on the other hand, has considerable latitude of movement and at occasional intervals is called upon to perform hard muscular work. The following table of respiratory volumes and rates per minute (Table IV.) corresponding to different work-equivalents is quoted from Haldane.[8]

TABLE IV.

—	Air breathed *in litres* per min.	Average volume *of each breath* in litres.	Number of *breaths* per min.
Rest in bed	7'7	.0'457	16'8
Rest standing ...	10'4	0'612	17'1
Walking 2 m.p.h....	18'6	1'27	14'7
Walking 3 m.p.h....	24'8	1'53	16'2
Walking 5 m.p.h....	60'9	3'14	19'5

The average respiratory volume per minute of 17 subjects in the sitting posture examined by Ellis[9] was 7·37 litres. The work done by an observer fighting his gun approximates to the work-equivalent of a man walking between two and three miles an hour.[10] Owing to the limited amount of compressed oxygen which can be carried in an aeroplane it was necessary to regulate the automatic delivery of oxygen so that it would last for the whole period of the flight, and a certain amount of economy was therefore imperative. It was eventually decided to supply sufficient for a man doing a work-equivalent of walking just over two miles an hour—i.e., breathing 20 litres per minute;† in other words, more than twice the amount actually required by the pilot or observer, provided they were sitting still. Against this it must be mentioned that no attempt was made to obviate loss of oxygen during expiration; this would have involved an expiratory valve and collecting bag, which would have added to the complexity and vulnerability of the apparatus, and also taken up valuable space. Judged subjectively in the air, and by the freedom from headache and fatigue after landing, the amounts supplied were ample, and officers thus supplied were known to carry out on the same day two reconnaissances of three hours each or more at 20,000 ft. without ill-effects.

The Reaction of the Human Organism to Lowered Partial Pressure of Oxygen.

All recent investigations have confirmed the views enunciated in 1876 by Paul Bert as a result of his experimental researches that the symptoms experienced under lowered barometric pressures are due not to the mechanical effects of the lowered pressure but to the fall of the partial pressure of oxygen. In other words, they are due to want of oxygen.

There are three experimental methods available for the study of oxygen-want in man. In the first the percentage amount of oxygen in the air breathed can be reduced, the atmospheric pressure being unaltered; secondly, the oxygen can be displaced from the hæmoglobin by adding to the air breathed a gas such as carbon monoxide with an affinity for hæmoglobin 300 *times greater than that of oxygen*; while thirdly, a steel chamber may be used in which the air pressure can be reduced at will by means of a pump. This last procedure was not practicable in France, although for long experiments it presents perhaps advantages over the other two; its disadvantage lies in the fact that the observer, like the observed, is the victim of oxygen-want, and his powers of making accurate observations are correspondingly impaired. The first method is capable of wide variations; here I will only mention two: (*a*) the re-breathing and (*b*) the *nitrogen-diluting methods. In the former the subject* breathes in and out of an enclosed space, his expired CO_2 being absorbed by caustic soda; in this way he gradually uses up the available oxygen and suffers from a progressive degree of oxygen-want, to which he would succumb were the experiment not terminated and the subject rapidly returned to ordinary air. The "altitude" attained by the subject is then calculated from the percentage of oxygen found by analysis of the air in the chamber at the end of the experiment. Depending on the amount of air originally available, the experiment will be short or long. The short, or bag, method (5 litres of air) has been employed by Flack[11] in this country, while the longer method (60 litres of air) has been extensively used in America. The main drawback to these methods is that the experiment is a progressive one, comparatively short, and it is impossible to maintain the subject at any given oxygen pressure; in terms of flying it is as if the pilot were to continue to ascend until he lost consciousness. It also involves the wearing of a nose-clip and breathing through a mouth-piece.

The nitrogen-diluting method devised by Dreyer[12] is based on the principle that if nitrogen is added to the air breathed it is possible to change at will the relative proportions of atmospheric air and of nitrogen, and so to change the partial pressure of oxygen. By this method the subject can be examined for any length of time and at any "altitude" desired, while the examiner is free to make the necessary investigations unhampered himself by lack of oxygen. Except for wearing a light face-mask, the subject is free to move all his limbs.

A. *Earlier Experiments.*

It was shown by Haldane and Poulton[13] in 1908 that whereas a rapid fall of oxygen in the inspired air is accompanied by great hyperpnœa, a more gradual diminution was associated with no evident hyperpnœa owing to the preformed CO_2 having time to escape. A still more gradual fall in O_2 pressure, especially if it were maintained, as in the long steel-chamber experiments of Boycott and Haldane,[14] gives time for an accumulation of acid substances, the result of imperfect oxidation, which will serve to reinforce the action of CO_2 in exciting the respiratory centre,[15] and therefore serve to ward off the effects of want of oxygen. The view that the CO_2 tension of the arterial blood, the carbonic acid acting by virtue of its acid properties, is the *physiological* stimulus to the respiratory centre, whereby the pulmonary ventilation is regulated to suit the requirements of the organism, has become an accepted faith in physiology and medicine as a result of the experimental investigations first of Haldane and secondly of Hasselbalch.[16] A rise of CO_2 tension such as results from exercise will stimulate the centre, and the corresponding increase in ventilation will tend to keep the CO_2 at a convenient level, at the same time, by raising the alveolar O_2 tension, providing oxygen for the increased needs of the body.

When the organism is subjected to lowered barometric pressures for a matter of days or more various adaptive processes come into play; of these we need here mention only one—viz., an increased percentage of hæmoglobin in the blood. This increase was ascribed in the Pike's Peak report[3] during the first few days partly to concentration of the blood and afterwards entirely to an increase in the total amount of hæmoglobin. Dreyer and Walker,[17] however, in an analysis of these results, but more particularly of data obtained by Abderhalden[18] on rabbits kept at St. Moritz (6000 ft.) concluded that the increase in the hæmoglobin percentage was attributable during the first day or two wholly to a diminution of blood volume effected by concentration of the blood at the expense of the plasma, and during the remaining period half to new formation of hæmoglobin and red corpuscles and half to blood concentration. When the animals were brought down to sea-level the blood volume was restored in two or three days, whereas the disappearance of the newly formed hæmoglobin and red cells occupied two or three weeks.

B. *Investigations During or Since the War.*

As a result of numerous examinations on flying officers by the nitrogen-diluting method, Corbett and Bazett[19] concluded that the normal reaction to a degree of oxygen-want corresponding to altitudes of from 15,000 to 19,000 ft. consists in an increase of pulse-rate of about 30 per cent., of pulse pressure of about 35 per cent., of pulmonary ventilation of about 50 per cent., and after about half an hour in some degree of blood concentration, as evidenced by a rise in the hæmoglobin percentage. The rise in pulse pressure is brought about by a gradual fall in the diastolic pressure until a new low level is reached, which is maintained, the systolic pressure remaining unaffected, or rising slightly. The increased ventilation is effected by a marked deepening of the breathing, the rate being little affected or even slowed. They further found that whereas in those who responded well there was a general correspondence in the intensity and time relations of the circulatory and respiratory reactions, this was often not so in those susceptible to reduced O_2 pressures. Their paper also shows that these responses occur early and gradually reach a maximum.

These findings have been confirmed and amplified by Schneider and his co-workers in America. Taking the initial reaction first, Ellis,[9] using the long rebreathing method, found in 23 out of 29 subjects an increase of respiratory volume at the end of the fifth minute, corresponding to an oxygen percentage of 18·1 (4000 ft.), and on restoring the subjects to ordinary air from very low O_2 percentages, a prompt return to the *normal* volume. Lutz and Schneider,[20] using the low pressure chamber and nitrogen-diluting methods, found in *both* a fall of alveolar CO_2 tension and increase of respiratory volume beginning at an "altitude" of 4000 to 5000 ft.; in each case the pressure was reduced or the proportion of nitrogen increased so as to correspond to an increase in altitude of 1000 ft per minute, which is approximately the rate of climb of the modern military aeroplane Similarly[21] acceleration of the pulse usually began between 6000 and 8000 ft and in every case before 9000 ft (i e , within nine minutes) By giving the subject pure nitrogen to breathe, a procedure which necessarily reduces the alveolar O pressure very rapidly, since under these conditions the venous blood will give up its O_2 to the alveolar air by diffusion, the quickening effect on the heart occurred within 15 seconds or less in 66 per cent of cases, and the respiratory volume increased within a similar period in 61 per cent On restoring the subject to normal air the pulse rate slowed within 15 seconds or less in 86 per cent of cases, and the respiratory volume decreased within 10 seconds or less in 89 3 per cent[22] In all cases the respiratory and circulatory responses developed before the subject appeared to come under any stress from lack of oxygen Mathison[23] had previously found that the systolic output of the heart in animals subjected to pure nitrogen rapidly increased to reach its maximum in 30 seconds

---

† Amount required can be calculated as follows: Of 20 litres of air 1/5th is O_2 = 4 litres. At 380 mm. Hg (18,000 feet) the partial pressure of O_2 is halved—i.e., half the required O_2 will be obtained from the air breathed, and half must be added artificially—that is to say, at 18,000 feet apparatus must deliver 2 litres O_2 per minute *measured at 760 mm. Hg.*

If now an individual be ' held " at an "altitude' for 60 to 120 minutes (as in flying) the reactions can be further studied Lutz and Schneider find that the pulse rate reaches a maximum about six minutes after 18 000 ft (382 mm Hg in steel chamber) has been attained, and 14 minutes after 19 500 ft (nitrogen method) The cyanosis also take a little time to reach its maximum After this latent period of a few minutes the pulse rate decreases in 72 5 per cent of cases, or remains unaltered in 22 5 per cent , and with this diminution in pulse the cyanosis gets less and the general condition improves Similarly the systolic arterial pressure remains unaltered, or rises slightly to fall again to its previous level, only in individuals who stand O_2 want badly is there a progressive fall In 70 per cent of cases the diastolic pressure gradually falls to a lower level which it maintains sometimes to rise again at a later period The pulse pressure follows the diastolic in inverse ratio[21] As regards the breathing, the alveolar CO_2 tension and respiratory per minute volume reach the former its minimum and the latter its maximum 5 to 10 minutes after 18 000 ft has been attained, after which the former tends to rise and the latter to fall to new levels, which are sustained The character of the breathing is deep and slow, with a tendency towards periodicity, while in no case was shallow breathing observed, and in only 2 out of 24 was the rate increased

The Changes Summarised

We may summarise these changes as follows In a large majority of healthy young men, during an ascent to 18,000 ft at the rate of 1000 ft per minute, the respiratory volume early begins to show a progressive rise, and the systolic output of the heart early and progressively increases until the maximum altitude has been maintained for some 5 to 10 minutes—i e , 20 to 30 minutes from the start of the experiment At this point the breathing and cardiac action tend to quiet down and the general condition improves

This improvement in a majority of cases synchronises with an increase of the hæmoglobin percentage in the blood, whether taken from the veins or capillaries This increase cannot be due to new formation of hæmoglobin and red cells, since it appears within 20 to 30 minutes, it must, therefore, be the result of withdrawal of fluid from the blood or of the throwing into the circulation of corpuscles which were previously side tracked For the latter hypothesis there is no experimental evidence, and it is difficult to conceive how or why such a thing could occur We must, therefore, assume that a concentration of the blood occurs which in some way relieves the circulation and (probably indirectly) the respiration[21] In 26 out of 47 experiments retardation of the pulse was associated with an increase in the hæmoglobin percentage up to 10 per cent , in all these compensation to oxygen want was good In 9 out of 47 a rise in hæmoglobin took place but was delayed, and the pulse did not slow , in these the compensation was inadequate[25]

Lutz and Schneider further point out that the respiratory and circulatory responses frequently show no correspondence either in their time relations or degree of intensity, that there are wide individual variations, and that the type of reaction may not always be the same in the same individual when tested on different occasions Moreover, in no case as Corbett and Bazett also found was complete compensation for altitudes of 18 000 to 19 500 ft ever observed, some degree of cyanosis was always present and the mental condition gradually failed with a tendency to go to sleep Further, headache and general fatigue were common after effects in the longer experiments and the alveolar CO_2 tension took some time to return to its normal figure

In what way blood concentration spares the heart is not clear The experimental records certainly seem to show a tendency for the diastolic pressure to cease falling or even to rise as the concentration becomes effective The primary fall of diastolic pressure is probably due to arteriole relaxation, and it is possible that the blood concentration increases the viscosity of the capillary blood to a degree sufficient to raise the diastolic pressure, but insufficient to produce capillary stagnation A high hæmoglobin concentration would certainly appear to facilitate the respiratory function of the blood as opposed to a low one, but the fact that, when sojourn at high altitudes is prolonged, the blood volume tends to increase pari passu with the formation of new hæmoglobin and red cells rather suggests that the reduction of blood volume is not altogether a convenient process

It has recently been shown by Kellaway[26] that in animals anoxæmia is readily productive of an increase of the blood sugar This increase is due to a direct stimulation of the central nervous system, which by splanchnic innervation causes a mobilisation of sugar directly by action on the liver cells, and indirectly by accelerating the output of adrenalin, which in turn acts on the liver In severer degrees of anoxæmia the want of O_2 apart from any stimulation of the nervous system, by its direct action on the suprarenals and possibly also on the liver, leads to hyperglycæmia How far this over production of adrenalin is responsible for the circulatory, respiratory, or blood phenomena which we have just discussed, it is impossible to say

COMPARISON BETWEEN ANOXÆMIA AND "SHOCK"

When an individual is exposed to still lower pressures of O_2 than those which we have studied the respiratory centre fails from fatigue, the blood pressure falls, and consciousness is lost

The failure of the heart is probably to some extent due to inadequate venous inflow, occasioned possibly by a rise of blood viscosity, and also, when the breathing fails, to a loss of the favourable influences exerted by respiration on the venous return by the aspiration of the thorax Defective venous inflow must necessarily be followed by defective systolic output, the blood pressure will fall, and the circulation come to an end A fall of venous pressure has, in fact, been recorded at high altitudes by several observers[27] More important, however, is the likelihood of the cardiac muscle itself becoming exhausted from want of oxygen It has been shown[28] that the heart may fail not only from being confronted with more work than it can do but also by a primary failure of its own metabolism In the second type of failure the rate of beat may be slowed, and a falling pulse rate in fatigued flying officers, tested close to their breaking point of oxygen want, has been observed by Corbett

Surgical shock and altitude sickness are both concerned with want of oxygen , in the latter the supplies are inadequate while in the former it is the transport of O_2 which is at fault The similarity of the bodily changes in shock and anoxæmia is, however, more apparent than real In both there is an increased rate of heart beat, but whereas the fall in systolic pressure occurs early in shock it is a terminal event in anoxæmia while the converse is true for the increased ventilation In both conditions it has been taught that there is an "acidosis" Concerning "acidosis" and the confusion which has resulted from the use of this polyvalent word further reference will be made Here it is only necessary to point out that the injection of a non volatile acid into the circulation does not produce "shock," while the view that "acidosis" is the cause of "shock" has been replaced by the view that an increase of acid substances occurs in "shock" owing to the defective tissue oxidation which results from the shock like condition[29] The final point of resemblance between shock and anoxæmia lies in the concentration of the blood which occurs in both The conditions under which shock occurred in the field especially favoured capillary stagnation and concentration of capillary blood , this must diminish the venous return to the heart and the arterial pressure therefore falls[30] The loss of water from the blood may in shock rapidly become extreme , in animals for example, after an injection of histamine a rise in the hæmoglobin percentage from 72 to 120 may occur within six minutes[31] In the experiments with low O_2 pressures, however, the rise is more gradual and rarely exceeds 10 per cent , and it appears, moreover, to be a favourable rather than an adverse factor Shock, in brief, is primarily a condition of circulatory depression or failure, while anoxæmia is essentially one of disturbed metabolism

ACCLIMATISATION.

An improvement in the condition of mountain-climbers during their stay at high altitudes was recognised long ago The improvement observed on Pike's Peak was attributed to three factors, which can be separately considered[5]

1 *Increased secretory activity of the lining cells of the lung alveoli*—It is common knowledge that the physiological world has for many years been divided into two schools of thought concerning the processes by which O_2 is transferred

from the alveolar air to the blood in the lung capillaries. On the one hand, it is affirmed, especially by Krogh[32] and his collaborators, that the physical processes of diffusion, involving a head of O_2 pressure greater in the alveolar air than in the blood of the pulmonary veins, is sufficient to explain the transfer at rest, during exercise, and during exposures to lowered O_2 pressures. Bohr, Haldane, and Barcroft[33] hold, on the other hand, that whereas diffusion will explain the conditions at rest, it will barely do so during exercise,[34] and certainly will not do so at high altitudes. Using the CO method for determining the tension of O_2 in arterial blood, it was found that on Pike's Peak this tension was greater than the alveolar O_2 tension, a result which can only be explained by secretion; whereas Krogh,[35] using the bubble aerotonometer finds that the arterial O_2 tension is always less than the alveolar, and the difference in tension, taken in conjunction with the amount of blood passing through the lungs per minute,[36] satisfies the diffusion theory under all conditions.

Unless secretion of O_2 by the lungs can be definitely shown to exist under physiological conditions such as exercise, the improbability of such a mechanism having been developed solely for the convenience of mountaineers or aviators becomes very great. There are, it is true, many *a priori* objections which can be adduced against the secretion hypothesis, and, as Bayliss[37] points out, it seems odd that although on Pike's Peak the arterial O_2 tension was always greater than the alveolar, it was nevertheless always less than the atmospheric O_2 tension; if secretion occurs, why should the secretory power always fail at this point? But a priori objections must give way to experimental facts, and it is better here to regard the question as being a divergence of opinion founded on a divergence of methods.‡

The important point to realise for our purposes is the fact, admitted by the supporters of the secretion theory, that the secretory powers, supposing that they exist, are inadequate, and the pulmonary epithelium fails to carry out satisfactorily the very small[39] amount of work it is called upon to do. Moreover, we know of no clinical methods by which these powers can be stimulated to increased activity.

2. *Lowering of the exciting threshold of the alveolar CO_2 tension.*—For an equal production of CO_2 the alveolar ventilation is greatly increased at high altitudes as compared with sea-level. This has been ascribed to the stimulating effect on the respiratory centre of the "lowered alkalinity" of the blood, so that the CO_2, being no longer the sole stimulus, its tension can be diminished without ill-effects. "Lowered alkalinity" of the blood has been recorded by numerous observers[40] at various altitudes, while a fall in CO_2 alveolar tension occurs early during an ascent, and is found in individuals living at such moderate elevations as 2200 ft.[41] (It does not, however, follow that because ventilation is increased that the blood is less alkaline (vide infra).) The increase in ventilation raises the alveolar O_2 pressure to a higher level than would otherwise be the case, and in this way constitutes an important factor in the compensatory process. That this occurs under flying conditions we have already seen.

3. *Increased percentage of hæmoglobin.*—The mode of production of this has already been discussed. The highest hæmoglobin percentage found among the Pike's Peak observers[3] was 134, with a red cell count of 7,800,000. In individuals who lived on the summit even higher figures were recorded—e.g., hæmoglobin 153 per cent., red cells 8,200,000. These changes imply a considerable increase in the oxygen capacity of the blood.

The stimulating effect of high altitudes on the blood-forming tissues had been previously recorded by many investigators,[42] and is evidently an adaptation evolved by the organism as a means of counteracting the effects of hæmorrhage. This valuable compensatory mechanism, as we should expect, however, is denied to the aviator, for of numerous flying officers examined under physiological conditions none was found to have an increase of hæmoglobin or of red cells.

4. *Circulatory changes.*—Except for a slight increase of pulse-rate no definite changes were observed on Pike's Peak after acclimatisation. For the flying man the matter is very different, and he responds vigorously to altitude by increasing the per minute output of his heart.

Evidence of Acclimatisation Among Aviators.

Many pilots state that they get accustomed to high altitudes when they first experience them. I was formerly of the opinion[43] that this merely meant that they get accustomed to the symptoms induced. There is, however, no question that the ability to withstand the effects, at least of short exposures, does increase in most individuals after the first few flights. Similar results have recently been obtained in low-pressure chamber experiments. In view of the rapid respiratory, circulatory, and blood reactions which constitute the normal reaction to high altitudes, this improvement would appear to be due to practice, and be of the same order as the improvement experienced by the athlete after a few short runs. In other words, practice facilitates the liberation of these reactions. That complete compensation never occurs is practically certain, and the cumulative ill-effects of a period of high flying clearly demonstrate that acclimatisation in the true sense of the word is unknown in the pilot.

In this connexion it may be asked whether a protracted period of high flying is capable of producing changes in the organs which can be recognised clinically. In other words, Is there a flying disease? This question can be answered in the negative as far as the conditions existing during the war permit of a definite answer being made. No organic changes in heart, lungs, or kidneys have yet been found which can be attributed solely to flying. Whether, however, prolonged and severe exposures to high altitudes without an artificial supply of oxygen are not able to effect changes in the nerve centres of a permanent character is not so certain, and there is, in fact, a certain amount of evidence that in rare instances such may be the case.[44]

THE REACTION OF THE BLOOD.

Before we can review the subject of anoxæmia we have to consider that much discussed and perplexing question, the reaction of the blood. It has already been mentioned that acidosis has been described as occurring in both shock and anoxæmia. Unfortunately the term acidosis is used by different writers to describe different conditions, while it is misleading in so far as it applies acidity, but in reality has very little to do with acidity. In this brief discussion I shall avoid it as much as possible.

The Maintenance of the Acid-alkali Balance.

It has recently become increasingly obvious that one of the balances which the organism is always striving to maintain is that between the acids and alkalies in the blood and tissues. This is not surprising when we consider the origin of life and the conditions under which life first appeared. It is, I believe, a fact that the salts of the blood are in the same relative proportions to one another as they are in sea-water, though in very different concentrations. In the blood of mammals the acid-alkali balance is represented by the ratio $\frac{H_2CO_3}{NaHCO_3}$ and the hydrogen-ion concentration of the blood—i.e., its acidity—is directly proportional to this ratio. If either the numerator or denominator is altered the organism will attempt to effect the necessary change, so that the ratio, and hence the H-ion concentration, or C_H, will be restored. It may, it is true, be restored at a higher or a lower level than normal, but at all costs it must be restored. There are several mechanisms made use of by the organism for maintaining this equilibrium. When an acid stronger than carbonic acid passes into the blood it displaces the CO_2 from an equivalent of bicarbonate, forming in its place its own sodium salt, as in the equation $HCl + NaHCO_3 = NaCl + H_2CO_3$. In this way the acid is neutralised and carbonic acid liberated. It is easy to understand that the change in C_H when acid is added to blood will not be nearly as great as when the same amount is added to water, for in the former the bicarbonate present will neutralise the acid ("buffer action") with the liberation of carbonic acid, the acid properties of which are very weak.[29] Nevertheless, the equilibrium has been disturbed to some extent since bicarbonate has been used up (diminution of "alkaline reserve"),[45] and the CO_2 in the system has been increased; in other words, the value of $\frac{H_2CO_3}{NaHCO_3}$ and, therefore, of C_H has been raised. It is generally accepted that *under physiological conditions* the value of C_H determines the activity of the respiratory (and possibly also the cardio-motor) centre, an increase augmenting its activity and vice versa.[15] In the example under discussion, therefore, the ratio $\frac{H_2CO_3}{NaHCO_3}$ will be brought back to normal by an increased ventilation, and consequent blowing off of carbonic acid out of the system.[46] In addition to the mechanism provided by respiration for keeping the ratio constant, the liver is capable of varying the output of NH_3, the kidneys of secreting excess of acid or alkali, whilst further regulation is provided by ionic interchange between plasma and corpuscles.[47]

Regarding the value C_H as the normal stimulus to the respiratory centre, and in view of the circumstance that the "alkalinity" of the blood had been found to be lowered in anoxæmia, the respiratory response to want of oxygen has been conceived to take place as follows. *Owing to* defective tissue oxidation acid substances appear in the blood which raise the $\frac{H_2CO_3}{NaHCO_3}$ ratio, to this rise the centre responds by increased activity, the ventilation is raised the alveolar O_2 tension tends to rise and so improves the oxidative *processes, while CO_2 is got rid of These effects* all tend to lower the ratio and restore it to normal

---

‡ Hartridge,[38] by observing the change of position of the absorption bands in the direction of the violet end of the spectrum when CO is breathed, found no evidence of O_2 secretion by the lung during violent but brief exertions.

In view, however, of the great rapidity with which the organism responds *to* lack of O_2, these explanations require reconsideration, for, although the respiratory centre is *admittedly a far more sensitive indicator to changes in* C_H than any which we can employ for measuring this value, it is a little difficult to believe that the effects of defective tissue oxidation with resulting rise of C_H can be transmitted *to the centre within a few seconds of breathing* pure nitrogen, or that they can be sufficiently great to excite the centre when the oxygen in the inspired air has only fallen to 18 1 per cent[22] These considerations recall the two views which have been held regarding the *stimulus to the centre, in one[6] it was maintained that the* centre could be directly excited by lack of oxygen, while in the other[13] that lack of oxygen, until the alveolar O_2 tension had fallen to 8 per cent, could only excite the centre indirectly by reinforcing the action of CO_2 by increasing the *acidity of the blood This divergence of opinion would* appear to be one of words rather than of principles, but it certainly appears reasonable to assume that the sensitiveness of the centre to H ions is determined by the oxygen tension in the arterial blood or in the centre itself[48] In this way we can account for the rapidity with which the centre responds to quite small diminutions of oxygen, while it leaves entirely undisturbed our conception of carbonic acid as the stimulus under physiological conditions As Starling points out, "the reactions of the organism have not been evolved in order to adapt it to balloon ascents or experiments in steel chambers"[49]

The Need for a Revision of Views

"Acidosis" not only *is* a bad name, it also *has* a bad name, a person with "acidosis" is a patient 'Acidosis,' moreover, has been conceived as being part of the anoxæmic condition Hasselbalch,[50] however, under conditions of O_2-want observed a diminution of NH_3 excretion and an unusually alkaline urine Why, then, when the body is suffering from an excess of acid does the liver diminish the production, and the kidney increase the excretion, of alkali? The assumption was that these organs were striving to maintain the level of acid as high as possible, that the organism, in fact, was trying to increase its acidity These urinary changes have more recently been confirmed by Haldane[51]

It has long been contended by Yandell Henderson[52] that "shock" is a state closely allied to acapnia, a condition brought about by excessive ventilation and washing out of CO_2 More recently Henderson and Haggard[53] have shown that this over ventilation, which if not antagonised would lower the $\frac{H_2CO_3}{NaHCO_3}$ ratio and so reduce C_H, leads, if not too violent, to a balance being struck at a lower level, in which, although the *alkali in the blood is greatly reduced* the ratio is restored In such a case the alkali is redistributed in the body, and probably, though it is not so stated, some is excreted in the urine This being so the inconvenience of defining "acidosis" as a reduction in the plasma *bicarbonate or "alkaline reserve"*[45] *becomes* evident, the alkali *must* be reduced under these conditions if equilibrium is to be restored to a level compatible with the survival of the organism

These facts suggest that the views hitherto current regarding *the reaction to lack of oxygen require revision* In the first place there is the initial response of the organism to the *stimulus* of O_2 want, consisting in an effort to maintain its supplies and transport of oxygen at an adequate level the CO_2 being left so to speak to look after itself Secondly, the increased ventilation must have the effect of lowering the $\frac{H_2CO_3}{NaHCO_3}$ ratio and decreasing the acidity This decrease shifts the curve of dissociation of oxyhæmoglobin in such a way that O_2 is less readily dissociated where the O_2 tension is low—i e, in the tissues where it is most wanted[51] Thirdly, it would appear that the fall in C_H is resented by the organism which attempts to counteract it by increasing the excretion and diminishing the production of alkali Fourthly, the decrease of ventilation which is associated with blood concentration will assist to raise the acid alkali balance, and so to diminish the alkalinity

INDIVIDUAL VARIATIONS TO WANT OF OXYGEN

The remarkable variations in the capacity of individuals to react to low O_2 pressures has long been recognised, and the experiences of the war have only accentuated them

In some individuals when tested experimentally the response is found to consist of an excessive cardio vascular or excessive respiratory reaction between the two there appears to be no correlation, and the unaided response tends rapidly to exhaust itself If now the respiratory pump is *working at a greater rate than the circulatory, if, that is to* say, more CO_2 is being got rid of than is being formed, the ratio $\frac{H_2CO_3}{NaHCO_3}$ must fall and the blood become more alkaline[4] It is suggested that this lack of coordination between the two reactions may explain some of the individual differences which are so often observed

SUMMARY

The flying officer reacts to altitude by an early increase of ventilation which tends to raise the alveolar oxygen tension, and by an early increase of the circulation rate which tends to improve tissue oxidation These reach a maximum, and then tend to diminish in *intensity, the diminution or "second wind," being* synchronous with, and presumably the result of, the development of a moderate concentration of the blood, as evidenced by a rise in the hæmoglobin percentage. The ensuing fall in ventilation will give the organism a chance to adjust the chemical reaction of its blood and tissue fluids which have been greatly disturbed in the direction *of alkalinity The adaptive processes* are, however, never *completely adequate for the* higher altitudes attained in war, and the individual is handicapped by an impairment of his mental activities, of which he is himself largely unaware, and is incapacitated physically when called upon for any extra exertion Moreover, the strain and fatigue of war are exaggerated by these repeated exposures, which serve to accelerate the processes of nervous and physical exhaustion

The conditions imposed by flying at high altitudes are wholly dependent on the fall in the partial pressure of oxygen, and the loss of efficiency thereby entailed can be avoided by the administration of oxygen and by nothing else

In this digression into the realms of physiology, the attractiveness of which in no way lessens its difficulties, I have in places had to traverse the same ground as that covered by my predecessor[5] of two years ago. Although I have avoided the use of the word "acidosis," I have reached, nevertheless the same conclusion as he—viz, that under certain abnormal conditions "acidosis" is of benefit to the organism, which has, *therefore, developed mechanisms for decreasing* its production and of raising its excretion of alkali The acid alkali balance of the body must be preserved, and once this equilibrium is upset the organism strives to restore it by every means at its disposal, or dies in the attempt

THE VITAL CAPACITY CONSTANTS APPLIED TO THE STUDY OF PULMONARY TUBERCULOSIS.

THE IMPORTANCE OF THESE CONSTANTS AS A GUIDE TO CLASSIFICATION AND AS A MEANS OF ASCERTAINING THE RESULTS OF TREATMENT.*

BY GEORGES DREYER, C.B.E., M.A., M.D.,
FELLOW OF LINCOLN COLLEGE; PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF OXFORD;
AND
L. S. T. BURRELL, M.A., M.D.,
ASSISTANT PHYSICIAN, BROMPTON HOSPITAL FOR CONSUMPTION.

IN THE LANCET of August 9th, 1919, one of us (G. D.) published a paper dealing with the normal vital capacity in man. In this paper it was shown that definite relationships between vital capacity and body surface, body weight, trunk length, and the chest circumference exist, expressed by the following formulæ:—

(i.) $\frac{W^n}{V.C.} = K_1$—where the power n is approximately 2/3, though more accurately 0·72.

(ii.) $\frac{\lambda^n}{V.C.} = K_2$—where the power n is approximately 2, though more accurately: in males 2·26, in females 2·3.

(iii.) $\frac{Ch.^n}{V.C.} = K_3$—where the power n is approximately 2, though more accurately: in males 1·97, in females 2·54.

Formulæ were also given which expressed the relationship between body weight, trunk length, and chest circumference respectively, as follows:—

(i.) $\frac{W^n}{\lambda} = K_4$—where the power n is approximately 1/3, though more accurately: in males 0·319, in females 0·313.

(ii.) $\frac{W^n}{Ch.} = K_5$—where the power n is approximately 1/3, though more accurately: in males 0·365, in females 0·284.

In all of the above formulæ—W = net body weight in grammes, λ = trunk length in centimetres, Ch. = circumference of chest in centimetres, V.C. = vital capacity in cubic centimetres.

It was also stated that different persons exhibit great differences in vital capacity, depending upon their occupation and mode of life. Thus persons living an athletic, healthy, outdoor life exhibit a greater vital capacity than persons living a sedentary life; that this difference in vital capacity in normal persons has nothing to do with fundamental bodily deficiencies is proved by the fact that properly regulated training and outdoor life can remedy this deficiency in vital capacity, as, for instance, boy scouting, army training, &c. The two sexes also differ, in the manner that the male has a greater vital capacity than the female.

The study of vital capacity in connexion with pulmonary tuberculosis is not novel, as John Hutchinson already in 1846 made use of vital capacity measurements as a help in the diagnosis of disease of the lung, more particularly tuberculosis. He showed that cases of this disease exhibited a lower vital capacity than that which he considered normal judging by the standing height of the individual. Quite recently the same subject has been carefully studied in a relatively small number of cases of pulmonary tuberculosis by Garvin, Lundsgaard and van Slyke, who also found that these cases showed a diminished vital capacity.

As we thought it was important to gain accurate quantitative information regarding the vital capacity in cases of tuberculosis of the lung by means of the above-mentioned formulæ, we decided to work jointly on the following line. One of us (L. S. T. B.) was to examine and make clinical notes of the patients, and also to take the various measurements required for the above formulæ, at the Brompton Hospital. The other (G. D.) to have no knowledge of the patients, but to form an opinion as to (1) classification, (2) prognosis, (3) the result of treatment—whether the patient was improving, remaining stationary, or getting worse, solely from the measurements supplied to him at Oxford. The only information given was the identification number of the patient, sex, age, occupation, and the measurements of weight, trunk length, circumference of chest, and vital capacity, while no information as regards the subject's condition was given, whether normal or diseased.

The procedures described in THE LANCET article of August 9th, 1919, for taking these various measurements are briefly recapitulated.

(1) Body weight = net weight without clothes in grammes.

(2) Trunk length in centimetres was taken by making the subject sit on a level floor with the knees flexed, the os sacrum, spine, and occiput being in contact with an upright measuring standard.

(3) Circumference of the chest in centimetres was taken at the nipple level in males, and just under the breasts in females, the subject being encouraged to talk and breathe naturally while the measurement was being taken.

(4) The vital capacity in cubic centimetres was obtained by taking five consecutive readings with a suitable spirometer. The subject was instructed carefully and patiently how to proceed, and encouraged to make the maximum effort.

Procedure for Calculation.

Since the publication of the above-named paper, tables have been prepared which are shortly to be published by Cassell and Co., where the vital capacity, corresponding to different weights, trunk lengths, and chest circumferences are given, as well as the normal weight corresponding to these measurements, for males and females. It has been found that for all practical purposes people may be grouped into three classes of different vital capacity—namely, A, B, and C—representing conditions of perfect, medium, and poor physical fitness. These tables have been used for the calculation of what the normal vital capacity should be in each case, paying due attention to the class the subject was likely to belong to according to his mode of life. The figure for vital capacity derived from the tables is always taken as equal to 100 per cent., and the individual is said to be normal, or minus, or plus so many per cent.

The reason for only making use of the vital capacity corresponding to trunk length and circumference of chest, and not of the vital capacity corresponding to the given weight in cases of pulmonary tuberculosis, often resulting in emaciation, is, that with loss of weight a vital capacity definitely abnormal when calculated in relation to the normal weight of the person might appear normal if calculated in relation to the reduced weight during disease. Whereas no such interference will be brought about when the vital capacity is calculated from trunk length, and only to a slight extent when calculated from the circumference of the chest.

Example:—Case No. 237.

Observation.

Male. Class A (ex-army). Age 20.	Chest circumference (Ch.) = 84·5 cm.
Trunk length (λ) = 88·0 cm.	Vital capacity (V.C.) = 2630 c.cm.

Calculation from Tables.

λ = 88·0 cm., gives vital capacity 4001 c.cm.
Ch. = 84·5 cm., gives vital capacity 4032 c.cm.

The mean of these two figures $\frac{(4001 + 4062)}{2} = 4031$ c cm is thus the calculated vital capacity derived from the observed measurements of trunk length and chest circumference As the patient's observed vital capacity is only 2630 c cm, his vital capacity is actually 34 8 per cent below normal (e g, – 34 8 per cent)

Before giving in detail those cases in which the vital capacity has been examined on more than one occasion, we give a general analysis of the first 200 cases, which include many where the vital capacity has only been examined on one occasion

Of these 200, four (Nos 15, 77, 124, 140) were patients who had had pulmonary tuberculosis with T B in the sputum, but had lost the T B after sanatorium treatment One of these (No 77) was returned as – 7 per cent Although at work and having no physical sign of active disease, he was easily tired and had not lost his cough His illness began with hæmoptysis three years ago One (No 15) was – 8 5 per cent, and has since got worse (see Table IIA) The other two were returned as normal Seventeen were cases believed to be healthy, and included some of the hospital staff sent as controls (without the knowledge of G D.), and certain patients in hospital for observation, but in whom no evidence of disease was discovered *All of these were returned as normal*

One patient (No 135) had been in a sanatorium for hæmoptysis, but no physical signs or T B have ever been found, the tuberculin test was negative, and there is no X ray evidence of lung disease He was returned as normal

Ten were cases of severe bronchitis (Nos 4, 12, 50, 84, 94, 97, 142, 146, 181, 199) Their vital capacities varied from – 10 4 per cent to – 35 per cent Two were believed to have debility only, and one of these (No 18), a boy of 18, showed a vital capacity of – 12 per cent. The other's (No 172) vital capacity was – 6 6 per cent (see Table III) One (No 180) with tuberculous glands was – 7 5 per cent (see Table IV) One (No 153) suffered from neurasthenia and tachycardia, and was – 30 per cent Six were boys of from 9 to 16 years of age, apparently free from tuberculosis, and of these one (No 6), with no clinical evidence of disease, was – 7 8 per cent, but later improved to + 3 7 after hospital treatment One (No. 7), aged 15, with no apparent disease, was – 12 per cent One (No 8), aged 13, is considered in Table IV. Two others (Nos 19 and 191) are considered in Table III The other (No 98) is considered in Table IIB (No 85) A patient with tuberculous glands (see Table IIB) Two patients had pleurisy only—No 150 (see Table IA) and No 11 (see Table IIA) Three (Nos 40, 131, and 166) died from pulmonary tuberculosis, their vital capacities being – 45 8 per cent four months before death in one case, – 71 9 per cent six weeks before death in another, and – 47 4 per cent six months before death in the third

The other 152 patients were definite cases of pulmonary tuberculosis, all were found to have a vital capacity of more than 10 per cent below normal, except (1) No 15 and (2) No 55 (see table), (3) No 115 (returned – 9 4 per cent, early good case, which did well), (4) No 139, (5) No 150 (6) No 157, (7) No 164, (8) No 168, (9) No 178, and (10) No 196 (see table)

In 116 cases the vital capacity has been taken on more than one occasion It was found to increase by at least 2 per cent in 44 cases *It was found to have decreased by at least 2 per cent in 39 cases* It varied less than 2 per cent in 27 cases In the remaining 6 cases it varied—sometimes increased, sometimes decreased

I —*Cases in which the Vital Capacity has Increased.*

We will deal first with the 44 cases in which the vital capacity has increased by at least 2 per cent.

A *Vital Capacity Increased by 2 per cent or more but less than 10 per cent*

1 No 35 Male, aged 40 Infiltration one apex Improved by hospital treatment and returned to work Is now about stationary Has fibrosis at the apex T B +, but signs not spreading

April, 1919 – 15 7 October, „ – 11 6	*March, 1920* – 12 0

2 No 53 Male aged 42 Early signs L apex Improved in hospital Can do light work T B +

May, 1919 – 23 3	February, 1920 – 15 6

3 No 67 Male, aged 51 Advanced disease L side T B + *Getting rapidly worse Artificial pneumothorax performed June, 1919 In bed for six weeks and then began to improve steadily* Is now at work and no T B Vital capacity has increased, although one lung is now completely collapsed

May, 1919 – 34 8 October, „ – 41 9 January 1920 – 38 8	March, 1920 – 34 8 April, „ – 32 8

4 No 74 Female aged 30 Advanced signs Fibrosis taking place Doing housework T B +

May, 1919 – 39 1 September, „ – 37 3	March, 1920 – 36 9

5 No 84 A *delicate boy of 9 Chronic bronchitis and asthma* No T B Keeping at school, much better during the present fine weather

May, 1919 – 24 4 February, 1920 – 26 6	April, 1920 – 16 0

6 No 126 Female, aged 27 Infiltration R apex T B + Improved at sanatorium No T B now, and very few signs

June, 1919 – 8 7	March, 1920 – 3 3

7 No 148 Male aged 30 *History seven years Fibrosis* L apex worse recently T B + Improved considerably at sanatorium Now at work

June 1919 – 16 4	March, 1920 – 7 6

8 No 150 Male, aged 30 History of pleurisy Signs of thickened pleura No evidence of active pulmonary tuberculosis Improved at sanatorium

June, 1919 – 6 7	March, 1920 – 3 0

9 No 175 Male aged 39 Slight signs one apex Improved in hospital Now at work T B +

September, 1919 – 21 1	March, 1920 – 15 0

10 No 183 Male aged 37 Considerable signs L lung Improved at sanatorium, and is now starting work again Still T B +

September, 1919 – 28 6 February, 1920 – 19 0	April, 1920 – 19 8

11 No 192 Female, aged 21 Advanced signs both lungs Has not lost weight and is able to get about Signs unchanged T B +

October, 1919 – 42 6	January, 1920 – 37 2

This case and No 256 illustrate well how the general condition of patients may be improved by hospital treatment even in advanced consumption

12 No 204 Boy, aged 17 Early signs L apex T B + Improved at sanatorium Still T B +

October, 1919 – 10 2 January, 1920 – 1 9	February, 1920 – 2 5 April, „ – 3 0

13 No 217 Male, aged 48 Slight signs one apex History 8 months T B + Improved at sanatorium Is now holding his own

November, 1919 – 27 3 *January, 1920* – 19 7	February, 1920 – 23 4 *April,* „ – 20 7

14 No 222 Male, aged 29 Infiltration R apex T B + Slightly better and is now in sanatorium

January 1920 – 21 5 February, „ – 19 4	March, 1920 – 19 4 April, „ – 18 7

In connexion with this case it is interesting to observe how very similar the vital capacity readings are They were taken at intervals of a month, during the patient's hospital treatment the last reading after 10 days at sanatorium It well illustrates that vital capacity does not vary in the same individual without variation in health

15 No 223 Male, aged 36 History three years One apex affected Improved after two months hospital treatment, January and February Is now doing light work T B +

January, 1920 – 21 2	*April 1920* – 16 3

16 No 230 Male, aged 23 Infiltration L apex T B + Improving in hospital

January, 1920 – 20 3	March 1920 – 16 1

17 No 234 Male aged 42 Bronchitis No T B and no signs of pulmonary tuberculosis At work

January, 1920, + 1 5	April, 1920 + 6 2

18 No 238 Male aged 28 Neurasthenia and debility No signs in lungs

January, 1920 – 3 7	April 1920 + 3 3

19 No 245 Male, aged 40 Slight signs and T B + in 1919 Left Frimley January 1920 *No T B now*

January, 1920 – 4 7	March 1920 – 1 0

20 No 256 Male aged 48 Advanced case, recently had breakdown Improved in hospital T B +

January, 1920 – 41 2	March, 1920 – 32 6

21 No 258 Male aged 40 *Advanced signs left lung* T B + and pyrexia a year ago Artificial pneumothorax performed May, 1919, and he is now better and working on a farm

January, 1920 – 39 3	April 1920 – 34 6

22 No 262 Male, aged 19 Early signs one apex T B +, Improved in hospital and is now in sanatorium

February, 1920 – 15 2	April, 1920 – 5 8

23 No 269 Female, aged 17 Early signs and T B + Improved in hospital and now in sanatorium

March, 1920 – 9 5	April, 1920 – 7 5

24 No 271 Male, aged 27 Acute infiltration R apex Improved and is now in sanatorium T B +

March, 1920 – 26 4	April, 1920 – 21 3

25 No 283 Male, aged 19 Acute infiltration one apex T B + Improved in hospital and is now at sanatorium

March, 1920 – 23 6	April 1920 – 18 3

In connexion with this series it is interesting to note that in no case do the vital capacity findings differ from the clinical observation of the patient

B *Vital Capacity Increased by more than 10 per cent*

26 No 6 Boy, aged 16 No definite signs Now at full work

April 1919 – 7 8	February, 1920 + 3 7

27 No 11 Boy, aged 17 In hospital for pleurisy No T B Improved in hospital and went to sanatorium in June Great improvement there and is now at work feeling well

31. No. 127. Female, aged 23. Early infiltration R. and L. apices. No T.B. found. Great improvement in sanatorium. Now at work.
June, 1919 – 38·8 | March, 1920 – 5·6

32. No. 129. Female, aged 28. Early signs one apex. No T.B. found. Great improvement in sanatorium. No signs now.
June, 1919 – 12·8 | March, 1920 + 7·6

33. No. 158. Male, 33. Infiltration both lungs. Fibrosis and steady improvement in sanatorium. T.B. +.
September, 1919 – 31·8 | April, 1920 – 17·8
January, 1920 – 22·9 |

34. No. 161. Male, aged 41. Early infiltration one apex. No T.B. Great improvement in hospital. Now full work.
September, 1919 – 27·5 | April, 1920 – 2·2
January, 1920 – 17·5 |

35. No. 181. Male, aged 37. Signs of bronchitis only. No T.B. Improved in hospital. Now at work.
September, 1919 – 10·4 | *March, 1920 + 2·3*

36. No. 189. Male, aged 30. Slight sign R. apex. T.B.+. Improved in hospital and lost the T.B. In sanatorium until April, 1920. No T.B. and no signs of activity now.
October, 1919 – 12·6 | January, 1920 + 3·9
November, ,, + 4·6 | April, ,, + 11·7

37. No. 208. Male, aged 39. Infiltration one apex. Improved in sanatorium. Now light work. T.B.+.
October, 1919 – 33·5 | March, 1920 – 22·3

38. No. 210. Male, aged 38. Severe bronchitis. No T.B. found. Improved in hospital.
October, 1919 – 36·2 | March, 1920 – 24·5

39. No. 212. Male, aged 19. Early infiltration R. apex. T.B.+. Still in sanatorium. Great improvement.
November, 1919 – 12·6 | February, 1920 – 3·7
January, 1920 – 4·9 | April, ,, + 1·7

40. No. 213. Male, aged 37. History nine years. Fibrosis L. lung. Infiltration R. lung. Considerable improvement in hospital. T.B. +.
November, 1919 – 41·0 | January, 1920 – 25·0

41. No. 214. Male, aged 36. Early infiltration one apex. T.B. +. Improved in hospital and is now in sanatorium. Slight relapse in January with coloured sputum.
November, 1919 – 29·6 | February, 1920 – 19·1
January, 1920 – 16·2 | April, ,, – 13·3

42. No. 216. Male, aged 30. Bronchitis following influenza. No T.B. Improved in hospital.
November, 1919 – 18·6 | April, 1920 – 7·2

43. No. 221. Male, aged 28. Good general condition, but T.B. +. Signs L. apex and repeated hæmorrhages. Artificial pneumothorax done October, 1919, but signs noted on R. side and L. lung allowed to expand again February, 1920. Good progress now.
January, 1920 – 59·9 | April, 1920 – 35·7
February, ,, – 58·1 |

44. No. 261. Male, aged 30. Infiltration one apex. Recently had pleurisy. Improving and now in sanatorium. T.B. +.
February, 1920 – 30·8 | April, 1920 – 20·4

II.—*Cases in which the Vital Capacity has Decreased.*

A. *Vital Capacity Decreased by 2 per cent. or more but less than 10 per cent.*

1. No. 15. Male, 34. Signs L. apex. T.B. + at first, but no T.B. on leaving sanatorium, April, 1919. Since then not so well.
April, 1919 – 8·5 | October, 1919 – 12·0

2. No. 28. Male, aged 44. T.B. +. Infiltration R. and L. apices. Went to sanatorium, but left not so well after six weeks.
April, 1919 – 25·2 | February, 1920 – 30·2

3. No. 50. Male, aged 43. Bronchitis and emphysema. No T.B No clinical change in his condition.
May, 1919 – 13·1 | February, 1920 – 17·7

4. No. 64. Girl, aged 18. Many signs R. apex. T.B. +. Slowly getting worse.
May, 1919 – 18·0 | October, 1919 – 23·9

5. No. 93. Male, aged 50. Infiltration R. apex. T.B. +. Went to sanatorium, but made no improvement. Slowly getting worse.
May, 1919 – 17·3 | March, 1920 – 23·3

6. No. 97. Male, aged 36. Severe bronchitis and asthma. Getting worse, and unable to work.
May, 1919 – 40·1 | February, 1920 – 49·5

7. No. 121. Male, aged 53. Infiltration R. apex. Getting worse. T.B. +.
June, 1919 – 28·5 | February, 1920 – 33·9

8. No. 135. Male, aged 23. Left sanatorium in May, 1919. No signs found there, and T.B. never found. Was sent to sanatorium because of hæmoptyses. Since leaving he has had several more hæmoptyses, but T.B. never found. Tuberculin test negative. X ray shows no sign of lung disease. The clinical evidence, therefore, agrees that he is not tuberculous.
June, 1919 + 14·0 | March, 1920 + 7·8

9. No. 139. Male, aged 30. Indefinite signs. T.B. + a year ago, but no T.B. June, 1919, or now. Recently has been losing weight and feeling easily tired.
June, 1919 – 5·2 | April, 1920 – 7·4

10. No. 152. Male, aged 34. T.B. + a year ago. Improved in sanatorium, and is still keeping at work but feeling run down, and cough has returned. No T.B.
September, 1919 – 13·0 | March, 1920 – 18·5

11. No. 155. Male, aged 23. Infiltration R. and L. apices. T.B.+. Went to sanatorium, but made no progress.
September, 1919 – 30·5 | March, 1920 – 37·9

12. No. 157. Boy, aged 17. Slight signs L. apex. Hæmoptysis. Went to sanatorium, but made no progress. Left in February and has been worse since. T.B.+.
September, 1919 – 5·8 | March, 1920 – 12·6
January, 1920 – 4·9 |

13. No. 176. Male, aged 30. Indefinite signs and no T.B. at first. Definite signs developed and T.B.+. In sanatorium, but not doing well.
September, 1919 – 5·4. | February, 1920 – 12·7
January, 1920 – 7·7. | April, ,, – 11·0

14. No. 184. Male, aged 25. Early case, following pleurisy. Is now in sanatorium, but not doing well. T.B. +.
September, 1919 – 19·8 | April, 1920 – 25·0
January, 1920 – 23·0 |

15. No. 196. Male, aged 32. Left sanatorium September, 1919. Returned to full work. Cough returned during winter, and he became worse. Keeping at work. Indefinite signs. T.B. +.
October, 1919 – 5·1 | April, 1920 – 12·7
January, 1920 – 14·4 |

16. No. 211. Male, aged 44. Advanced signs L. lung. Artificial pneumothorax done May, 1919. Considerable improvement, and he went to sanatorium. Had influenza in March, and was in bed for three weeks. Improving again now. T.B. +.
November, 1919 – 54·8 | April, 1920 – 60·2
January, 1920 – 51·8 |

17. No. 244. Male, aged 31. Infiltration R. apex. Is now in sanatorium, but not improving. T.B. +.
January, 1920 – 20·6 | February, 1920 – 24·5

B. *Vital Capacity Decreased by 10 per cent. or more.*

18. No. 21. Male, aged 35. Infiltration one apex. T.B. +. Went to sanatorium but left in September, 1919, having made no progress and is now much worse.
April, 1919 – 20·6 | February, 1920 – 36·9

19. No. 22. Male, aged 62. Infiltration both apices. T.B. +. Getting worse and signs extending.
April, 1919 – 18·0 | February, 1920 – 33·6

20. No. 24. Boy, aged 18. Early signs left apex. Spread to R. lung. Now advanced signs both lungs. T.B. +.
April, 1919 – 13·0 | April, 1920 – 40·6
January, 1920 – 37·5 |

21. No. 41. Male, aged 39. Out-patient. Advanced signs. Much worse. T.B. +.
April, 1919 – 32·9 | April, 1920 – 57·4

22. No. 52. Boy, aged 19. Early infiltration. T.B. +. Went to Frimley and got much worse. Now in bed at home.
May, 1919 – 11·1 | February, 1920 – 27·9

23. No. 54. Male, aged 34. Extensive signs left lung, following pleurisy. T.B. +. Got worse, but went to Frimley and held his own. Not doing well.
May, 1919 – 23·7 | April, 1920 – 35·3
January, 1920 – 40·1 |

24. No. 55. Boy, aged 18. Early signs R. apex. Disease spreading rapidly. T.B. +.
May, 1919 – 8·2 | September, 1919 – 23·0

25. No. 58. Male, aged 39. Long history. T.B.+. Active signs R. lung.
May, 1919 – 29·1 | May, 1920 – 40·0
February, 1920 – 36·6 |

26. No. 62. Male, aged 33. Advanced disease. Attending out-patients and steadily getting worse. T.B.+.
May, 1919 – 48·1 | March, 1920 – 62·1
October; ,, – 53.9 |

27. No. 78. Male, aged 31. Hæmoptysis and signs L. apex. T.B.+. Artificial pneumothorax done March 1919. Apparently holding his own and no T.B. now.
May, 1910 – 40·5 | March, 1920 – 50·7
October, ,, – 49·0 | April, ,, – 51·8

28. No. 79. Female, aged 30. Signs R. and L. lungs. Getting worse. T.B.+.
May, 1919 – 21·0 | October, 1919 – 35·7

29. No. 85. Boy, aged 16. Tuberculous glands of neck and old peritonitis. In February, 1920, he was clinically better. Is now in sanatorium.
May, 1919 – 7·7 | February, 1920 – 17·9

30. No. 98. Boy, aged 13. Debility, but no sign of organic disease. Is still attending school. Looks very delicate, but no definite physical signs.
May, 1919 + 2·2 | April, 1920 – 8·5
February, 1920 – 3·0 |

31. No. 107. Boy, aged 18. Signs R. and L. lungs. *Poor condition* and T.B. +, though just returned from sanatorium, May, 1919. Since then getting steadily worse.
May, 1919 – 25·2 | February, 1920 – 40·4
October ,, – 35·5 | April ,, – 39·4

32 No 168 Male, aged 29 Early infiltration R apex Went to sanatorium but failed to improve Since leaving in January he has been much worse T B +.

September, 1919 – 5 6 | March, 1920 – 20 1
January, 1920 – 9 7 |

33 No 171 Male, aged 26 *Indefinite signs* T B + Went to sanatorium but made no improvement Since leaving in November, he became worse Definite signs at R apex now found

September, 1919 – 7 6 | April, 1920 – 23 4

34 No 178 Male, aged 20 Slight signs L apex T B + Went to sanatorium but became much worse Now living at home and not working

September, 1919 – 2 2 | March, 1920 – 25 7
January, 1920 – 25 7 |

35 No 205 Male, aged 30 Extensive disease spreading quickly in left lung T B + Artificial pneumothorax done in October, 1919, since when his temperature has been *normal*, but he is slowly losing ground

October, 1919 – 22 2 | March, 1920 – 46 7
January, 1920 – 42 1 |

36 No 229 Male, aged 51 Extensive signs Much worse T B +

January, 1920 – 39 2 | April, 1920 – 59 4

37 No 251 Male, aged 30 Extensive signs left lung T B + Pyrexia and signs spreading. Artificial pneumothorax done in March, since when he has improved

January, 1920 – 38 2 | April, 1920 – 64 1

38 No 252 Male, aged 46 Signs both lungs T B + Much worse

January, 1920 – 44 4 | April, 1920 – 58 6

39 No 254 Male, aged 23 Signs both lungs T B + Much worse and now bedridden

January, 1920 – 38 9 | April, 1920 – 70 6

III —*Cases in which the Vital Capacity has Varied by less than 2 per Cent.*

1 No 5 Male, aged 39 Fibrosis L lung T B + Clinically, slightly worse and going down hill Not working, attending out patients

April, 1919 – 50 0 | February, 1920 – 50 6

2 No 19 Schoolboy, aged 13 No definite physical signs Looks delicate and has dyspnœa X ray evidence of bronchial glands

April, 1919 – 23 1 | April, 1920 – 23 6
February, 1920 – 27 5 |

3 No 27 Boy, aged 18 Acute infiltration left lung and slight R T B + following influenza Improved in hospital and sanatorium, but is now unable to work

April, 1919 – 39 2 | February, 1920 – 39 2

4 No 57 Male, aged 45 Infiltration R and L lungs Improved *in sanatorium and is now attending out-patients* T B +

May, 1919 – 63 3 | February, 1920 – 61 9

5 No 76 Girl, aged 18 Extensive fibrosis *Condition stationary* T B +

May, 1919 – 35 7 | February, 1920 – 33 8

6 No 69 Female, aged 21 Acute signs R and L lungs Settled down and now able to get about T B +

May, 1919 – 33 5 | February, 1920 – 32 5

7 No 106 Male aged 45 Previously T B + Now signs of fibrosis, but no T B Keeping at work Disease apparently stationary

May, 1919 – 30 1 | February, 1920 – 29 5

8 No 145 Boy, aged 14 No signs of disease Keeping fit and at school

June, 1919 – 0 1 | March, 1920 – 1 0

9 No 147 Male, aged 31 *No clinical evidence of disease*

June, 1919, + 6 1 | March, 1920 + 4 0

10 No 149 Male, aged 40 *Indefinite signs* T B *never found* keeping well

June, 1919 – 2 5 | March, 1920 – 1 0

11 No 156 Male, aged 19 No definite signs No T B Keeping well

September, 1919 – 3 7 | March, 1920 – 1 7

12 No 172 Man, aged 26 Delicate and occasional evening pyrexia No definite signs and no T B found

September, 1919 – 6 6 | February, 1920 – 4 3
January, 1920 – 16 1 | April, ,, – 6 6

In this case the patient had been in bed with mild influenza in January

13 No 179 Male, aged 28 Infiltration R apex T B – Holding his own

September, 1919 – 17 0 | March, 1920 – 18 3

14 No 185 Male, aged 23 T B + Infiltration both apices No change

September, 1919 – 33 5 | January, 1920 – 33 7

15 No 190 Male, aged 54 Chronic case Fibrosis R lung T B + Keeping at work

October, 1919 – 13 5 | April, 1920 – 12 9
January, 1920 – 14 5 |

16 No 191 Boy, aged 11. *No definite signs of disease*

October, 1919 – 8 8 | March, 1920 – 6 1

17 No 209 Male, aged 29 Slight infiltration left apex No T B Delicate, and disease apparently now arrested

October, 1919 – 12 2 | April, 1920 – 12 5
January, 1920 – 20 5 |

18 No 219 Male, aged 30 No definite signs and good general condition T B +

January, 1920 + 13 9 | April, 1920 + 15 0

19 No 227 Boy, aged 18 No physical signs

January, 1920 – 1 2 | March, 1920 + 0 3

20 No 228 Male, aged 41 Slight fibrosis base of one lung No T B Well and at work

January, 1920 – 1 4 | April, 1920 – 0 9

21 No 236 Male, aged 30 Infiltration both lungs T B +. Just gone to sanatorium

January, 1920 – 40 6 | February, 1920 – 39 4

22 No 239 Male aged 39 Few signs L apex T B + Just gone to sanatorium

January, 1920 – 12 5 | April, 1920 – 13 8
March ,, – 10 4 |

23 No 246 Male, aged 27 Infiltration both lungs T B +. No change

January, 1920 – 42 6 | March, 1920 – 41 0

24 No 255 Male, aged 26 Early case Infiltration R apex. T B + Just gone to sanatorium

January, 1920 – 6 9 | February, 1920 – 7 9

25 No 257 Male, aged 51 Chronic case Artificial pneumothorax for over two years Stationary condition

January, 1920 – 48 4 | April, 1920 – 46 7
March, ,, – 46 9 |

26 No 266 Male, aged 28 Infiltration R apex T B + No apparent change

February, 1920 – 24 0 | April, 1920 – 23 4

27 No 267 Male, aged 25 Indefinite sign At sanatorium No T B

February, 1920 – 1 5 | April, 1920 – 0 3

IV.—*Cases in which the Vital Capacity Varied—sometimes Increased, sometimes Decreased.*

1 No 8 Boy of 13 Delicate and has had pleurisy No definite physical signs, and his condition was apparently the same on all three examinations

April, 1919 – 25 1 | April, 1920 – 21 0
February, 1920 – 30 2 |

2 No 25 Male, aged 42 This patient was bedridden T B + Extensive signs R lung, for which an artificial pneumothorax was done in March, 1919 *After this he improved and is still able to get* about Clinically his condition is much better than in April, 1919, but about the same as, or slightly worse than, in October, 1919

April 1919 – 59 7 | March 1920 – 56 1
October, ,, – 26 9 |

3 No 37 Female, aged 21 Extensive signs both lungs with fibrosis She improved in sanatorium which she left in August, 1919 Apparently holding her own since T B +

April, 1919 – 22 2 | March, 1920 – 21 0
September, ,, – 14 9 |

4 No 180 Male, aged 24 Enlarged glands of neck No other evidence of tuberculosis Keeping well and at work No clinical reason for variation in vital capacity

September, 1919 – 7 5 | April 1920 – 6 8
March, 1920 – 21 1 |

5 No 207 Male, aged 31 Very advanced signs one lung T B +. Artificial pneumothorax March 1920 since when he was able to get about, and is apparently holding his own

October, 1919 – 56 1 | March, 1920 – 45 7
January, 1920 – 36 5 |

6 No 215 Male, aged 39 Infiltration R and L lungs T B + History two years Apparently remaining stationary

November, 1919 – 42 1 | February 1920 – 40 3
January, 1920 – 30 6 | April – 31 7

Conclusions.

From the careful analysis of the cases given in detail above, the following conclusions seem to be justified.

1. In cases of pulmonary tuberculosis there is a definite decrease in vital capacity as compared with what should be normal for any individual, taking into account the class in which this individual should be placed according to occupation and mode of life

2 An improvement in the clinical condition of the patient is found to be accompanied by an increased vital capacity, while an advance of the disease results in a decrease in vital capacity. The vital capacity, therefore, gives a valuable quantitative measure of the benefit, if any, which a patient receives as the result of treatment.

3 The determination of the vital capacity is useful for the classification of cases of pulmonary tuberculosis, because it is possible by this means numerically to express the injury to health (e g, degree of toxæmia) which otherwise would depend on the individual interpretation of physical signs by different observers. In this connexion it should be noted that classification by physical signs alone may place a patient nearing death from an acute lesion in a high category, while another

patient, with satisfactory fibrosis and extensive cavitation, likely to live for several years, may be placed in the lowest category.

4. As an aid to diagnosis a single or repeated examination of the vital capacity of doubtful cases will also prove useful. If a normal vital capacity is found in such cases, the patient is most unlikely to be suffering from pulmonary tuberculosis, whereas if the vital capacity is much decreased the patient should be suspect, though it must always be borne in mind that other diseases may also cause a lowering of the vital capacity.

5. Finally, a systematic study of the vital capacity in its proper relationship to body size has given important information as to the beneficial effects of different treatments of pulmonary tuberculosis, and has made it possible to distinguish quantitatively the degrees of improvement.

Our thanks are due to Dr. J. J. Perkins and other members of the staff of the Brompton Hospital, who kindly have placed their cases at our disposal for this investigation. We also wish to thank Dr. F. G. Hobson, D.S.O., and Mr. G. F. Hanson, late Lieutenant, U.S.A. Medical Air Service, for kind help in various ways.

BLOOD TRANSFUSION:

ITS THEORY AND PRACTICE.[1]

BY GEOFFREY KEYNES, B.CH., M.D. CANTAB.,

ASSISTANT, PROFESSORIAL SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL.

SINCE the end of the war there has ceased to be any pressing need for doing blood transfusion on a large scale, and its great importance has therefore tended to fall into the background. However, it constitutes one of the biggest advances that has resulted from the practice of military surgery, and it is thus desirable that knowledge of the methods employed should be diffused as widely as possible.

Probably few lectures on blood transfusion given have been without a reference to the transfusion supposed to have been performed in 1492 upon Pope Innocent VIII., the authenticity of which must, however, be discredited. It is, on the face of it, improbable that a blood transfusion should have been attempted before the discovery, about 1616, of the circulation of the blood. The truth is that in order to restore the Pope's health three boys were bled to death and a draught prepared from their blood, but that this failed of its effect. It is of much greater interest to notice that in Sprat's History of the Royal Society, 1667, it is recorded that the versatile Sir Christopher Wren "was the first Author of the Noble Anatomical Experiment of Injecting Liquors into the Veins of Animals. By this Operation divers Creatures were immediately purg'd, vomited, intoxicated, kill'd, or reviv'd according to the quality of the Liquor injected. Hence arose many new Experiments, and chiefly that of Transfusing Blood, which the Society has prosecuted in sundry instances, that will probably end in extraordinary Success." In my own copy of the book an eighteenth century hand has written large in the margin "It failed," and that was the fate of most subsequent attempts. It has been left for a later age to achieve the "extraordinary success" predicted two and a half centuries ago.

Indications for Blood Transfusion.

It is first necessary to consider what are the indications for blood transfusion; these may be stated shortly as (1) collapse due to any sudden and severe loss of blood, with or without the additional collapse-producing factor introduced by "shock"; and (2) anæmia due to slow and prolonged loss of blood corpuscles by hæmorrhage or by pathological destruction.

It was unusual during the war to meet with patients who were in danger of their lives from loss of blood alone without the presence of traumatic shock, but such cases did occur, and they will also be met with in civil practice—as, for instance, in attempted suicide by throat cutting, in gastric ulcer with severe hæmatemesis, in secondary hæmorrhage after operation, and in hæmophilia. The more typical condition following war wounds—hæmorrhage with traumatic shock—will be faithfully reproduced in the victims of train or street accidents, in patients who have undergone certain severe operations, and in women suffering from post-partum hæmorrhage or a ruptured ectopic gestation.

The signs and symptoms of acute anæmia need not be detailed here, though it may be mentioned that the "amaurosis" of the text-books is not a symptom that is commonly met with in practice. The signs that are of the most use are the pulse-rate, the blood pressure, and the hæmoglobin content. It has been stated that a blood pressure below 70 mm. of mercury is scarcely compatible with life, but this is not in accordance with experience. It was common in France to meet with blood pressures below 45 mm., so low, in fact, that they could scarcely be measured, but many patients whose lives had reached even so low an ebb as this were quickly restored by the administration of blood, provided that the exsanguined state had not lasted for too long a time. It is doubtful how far blood transfusion is of use in the treatment of shock unaccompanied by hæmorrhage, since the condition here is largely one of an increased viscosity of the blood with accumulation of the corpuscles in the capillaries. Should blood transfusion be proved to have more effect than other restoratives it will be administered in much smaller quantities than are necessary for the treatment of hæmorrhage. Blood transfusion has been found of the greatest service in the treatment of hæmophilia, for not only can the blood lost be thus replaced, but also it is found that the introduction of the normal blood temporarily confers upon the patient's blood the power of coagulation, so that the bleeding ceases. This effect is not interfered with by the presence of an anticoagulant in the transfused blood. Evidence is accumulating that blood transfusion can be used with good effect in pernicious anæmia, and there is little doubt that blood is destined to be an important therapeutic agent in the treatment of blood diseases.

The Quantity of Blood to be Given.

In considering how much blood should ordinarily be given in the treatment of acute anæmia, experience is a safer guide than any theoretical considerations.

It is difficult to estimate accurately the total quantity of blood in the body of an adult, but it has been variously stated by physiologists to be from seven to ten pints. It is still more difficult for obvious reasons to estimate how much blood a man can lose and yet remain alive. This will depend partly on the power of physiological accommodation possessed by the individual in his vaso-motor system and tissue fluids, and partly on the rapidity with which the bleeding takes place. Under certain circumstances it is better that the bleeding should be at first more rapid than can be compensated for by these processes, for the immediate syncope which results produces so great a fall in blood pressure that hæmorrhage almost ceases, with the result that a clot forms in the lumen of the divided vessel. Experience shows us that hæmorrhage may take place into the peritoneal or the pleural cavities to the extent of three pints or more, and it may be stated as a rough guess that four pints, or possibly as much as half the total blood volume, may be lost without immediate death resulting. It is interesting to find that in the treatment of hæmorrhage it is not necessary to administer an amount of blood even approaching these quantities, for in most cases the balance between the volume of the circulating blood and the output of the heart is sufficiently restored by the administration of 650 to 1000 c.cm. of blood. Further fluid can then be given by the mouth or by the rectum. It may sometimes happen that a patient already in extremis from loss of blood needs a severe operation, and in such a case two transfusions of 800 c.cm. each may be given with advantage, the first to revive the patient, the second to combat the additional shock and hæmorrhage caused by the operation. The gum-arabic solution, which was introduced in the last year of the war as a substitute for blood, did not in practice altogether justify the hopes that had been founded on the good results obtained in the laboratory; it is certainly better than the normal or hypertonic saline formerly used for transfusion, but blood, when obtainable, is still better.

Relative Importance of Corpuscles and Serum.

The mention of gum introduces the question as to whether it is the corpuscles or the serum that is the more important constituent of the transfused blood.

Doubt has been expressed as to whether the transfused corpuscles carry out their function as oxygen carriers in the recipient; but since it has been proved that the corpuscles of transfused blood can both live and keep their normal appearance for more than 30 days in the recipient's circulation, it seems reasonable to suppose that they are functional Permanent restoration of blood volume is undoubtedly the chief result to be aimed at, but the physiological functions of all the constituents of the transfused fluid cannot be regarded as unimportant It is possible that the foreign blood has the power of stimulating the regeneration of blood cells and of restoring the tone of the body generally, but this is a subject which demands further investigation

"*Blood Groups*"

Much has been written during the past two years on the division into "blood groups" and its practical application

For practical purposes human beings have been divided into four groups, according to the agglutinating reaction of their bloods, and this has eliminated the fatalities which used to result from transfusion with blood which is incompatible with that of the patient There can seldom be any reason at the present time for performing a transfusion without first testing the donor for his blood group, since the sera of Groups II and III can always be kept in stock and the test of donor and recipient performed in a few minutes[2] Some operators have preferred to use a donor of the same group as the recipient rather than a member of Group IV, the so-called "universal donors", but there is no evidence that this confers any advantage It is true that the serum of Group IV agglutinates the corpuscles of all the other groups outside the body, theoretically this is an objection to the indiscriminate use of Group IV for transfusion, but as no ill effects result such agglutination presumably does not occur in the body This is interesting, because the amount of transfused blood is considerable relatively to that in the patient, and it must be presumed that the changes which occur in the body are different from those obtained outside it It has been suggested that the agglutinin is inactivated by the recipient's serum The blood groups depend upon differences in individuals, which are presumably inherited in a definite manner, since their numbers are found to maintain a constant proportion in any large population Although there seems to be some racial variation in the distribution of the blood groups, no physiological advantage, such as immunity to disease, has been demonstrated in connexion with them, and it would therefore be expected that inheritance would be carried on without the interference of natural or artificial selection Blood groups have been found among some animals, such as dogs, but others, such as rats and mice, do not seem to possess them Some authorities have even stated that a baby does not show its characteristic blood group for the first two years of its life, but gives the same reaction as its mother This does not agree with my own observations, which have shown that a baby may be of a different group from both its mother and father immediately after birth, and that the group does not change as the child grows older

The choice of a donor will therefore depend primarily upon his belonging either to Group IV or to the same group as the recipient It is necessary to make very careful inquiries for any history of a communicable blood disease, such as malaria or syphilis in the donor, his Wassermann reaction should be tested if possible The effect on the donor of the withdrawal of blood is never more than a transient faintness and varies very much with the individual One man, large and robust looking, may become faint after losing 400 c cm or less, another, to the eye less physically fit, may part with 1000 c cm and show no signs whatever The effect probably depends more on the donor's mental attitude towards the process than on the amount of blood lost

Disadvantages of Methods of Transfusion Formerly Used

All the earlier methods of transfusion depended on the direct transference of blood from the donor's arterial system to a vein of the recipient, but this process presents several disadvantages, the chief of which is the impossibility of knowing how much blood has been transfused The technical difficulties, too, are very great, even with the help of various ingenious devices, and the method is now chiefly of historical interest

A great improvement was introduced by the "paraffin tube" method the blood being allowed to run from the donor's vein into a vessel coated on the inside with paraffin and being transferred at once to the recipient This method allows of measurement of the amount of blood transfused, and the blood can be given without the admixture of any foreign substance, but other objections remain, the chief of which are the great difficulty of carrying out the process of paraffining a glass vessel quite perfectly, the absolute necessity for injecting the blood into the recipient immediately after it has been drawn and the fact that an open operation to expose the vein of the donor cannot be avoided The ideal method of blood transfusion seems to me to require that it shall be absolutely certain of success that the blood need not be injected immediately so that other circumstances besides the demands of the transfusion may be allowed for, and that no injury shall be done to the donor beyond the puncturing of a vein In addition to this the method should be so simple and free from special apparatus that it can be easily learnt and carried out by one operator without skilled assistance Blood transfusion is a life saving operation which should be capable of being carried out in a hospital by a house surgeon at the shortest notice, and an extensive experience should not be necessary in order to ensure success

The Citrate Method

All these requirements are fulfilled by the citrate method, and it is, I think, the method which should be taught at the present time

The blood can be drawn with the minimum amount of injury to the donor, when drawn it can be put on one side for several hours if necessary, and then given to the patient at whatever may be judged to be the best moment, the whole process can be carried out by a single operator unaided, and, finally but little practice is needed to make success certain every time The sodium citrate, with which the blood is mixed, forms a soluble compound with the blood calcium, which is thereby rendered inert as regards the coagulation reaction It may be objected that sodium citrate is a toxic substance and should therefore be avoided but the amount used is not large enough to produce any appreciable reaction in most patients I have been in the habit of using 160 c cm of a 3 8 per cent solution as was originally recommended by Robertson for any quantity of blood up to a litre, this amount may err on the side of excess, and it has been recently stated that 100 c cm of a 3 8 per cent solution is enough

Description of Apparatus and Technique

The transfusion apparatus known as "Robertson's bottle," first described by Oswald Robertson in 1918 is the basis of most citrate methods I soon found that it could be modified in the direction of simplicity, since in drawing the blood there is no necessity to create a negative pressure if a needle of a large enough bore (2 or 3 mm) be used (Fig 1)

FIG 1 —Needle used for blood transfusion (full size) The bore should be 2 or 3 mm

The needle should be kept ready for use in liquid paraffin and after use should always be re sharpened on a bevelled hone When the donor's arm has been congested and a suitable vein chosen (usually the median basilic) the area of puncture is infiltrated with novocain, it is then only necessary to make a tiny cut in the skin with the point of a scalpel and to push the needle through into the vein The blood is then allowed to flow through a rubber tube, which hangs freely into a flask (Fig 2) containing the citrate and as it flows in it is thoroughly mixed with the citrate by gently swinging the flask It is convenient to use a graduated conical flask provided with a side tube and holding about a litre

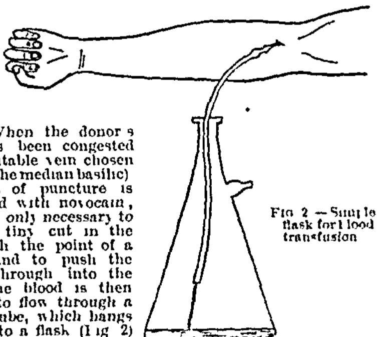

FIG 2 — Simple flask for blood transfusion

If a properly adjusted tourniquet is kept on the donor's arm while he works his forearm muscles by clasping and unclasping his hand a flow of blood is obtained which is fast enough to prevent clotting in the needle and indeed, quite as fast as most donors can stand. Blood up to 1000 c.cm. can be collected in this way in 10 to 20 minutes.

---

[2] For a tabulation of the groups and their reactions see an article by A Fleming F R C S and A B Porteous, M B, in THE LANCET for June 7th 1919

As an additional precaution a few drops of paraffin may also be run through the rubber tube before drawing the blood. The flask of citrated blood can then be stood in a basin of warm water and put on one side until wanted or taken to the patient's bedside. When the needle has been withdrawn from the donor's vein, slight pressure must be maintained for a few minutes on the puncture with a swab to prevent any bleeding, but no suture is needed.

In the administration of the blood it is usually best to expose the median basilic or saphenous vein in the patient by an open operation. If the case is one of hæmorrhage or shock the patient's veins will be collapsed, and the direct introduction of a needle will sometimes be found difficult.

In giving the blood I have found it of great advantage to fix on the delivery tube of the flask an air-lock, as shown in Fig. 3. The barrel of this air-lock, with a rubber tube and cannula attached, is first filled with normal saline solution and the tube near the cannula is clipped. The cannula is then inserted in the patient's vein and tied in. The barrel is fitted on to the rubber bung through which the nozzle of the delivery tube projects, the clip is released, and slight positive pressure is produced in the flask by means of a rubber bulb attached to the side tube. The citrated blood rises in the delivery tube, displacing the saline solution in the air-lock to a lower level, and then flows from the delivery tube into the air-lock, displacing the rest of the saline solution, and so into the patient's vein. The introduction of the air-lock has two advantages: in the first place, it allows of the cannula being filled with saline, so that during the insertion in the vein there is no leakage of blood which would obscure the operation; in the second place, it is easy to regulate with nicety the time occupied in giving the blood and to be quite sure that it is flowing properly. If the patient is suffering from acute anæmia, 750 c.cm. of blood may be given in the course of 20 minutes; but if the condition is one of chronic anæmia due to a slow continuous oozing, the blood must be given much more slowly. It is dangerous in such cases to increase the blood volume rapidly, and three-quarters of an hour must be occupied in giving 500 c.cm.; even then the patient may complain of a feeling of tightness in the chest and dyspnœa, due to embarrassment of the right heart, during the transfusion. The apparatus can also be used with advantage in giving saline solution or gum.

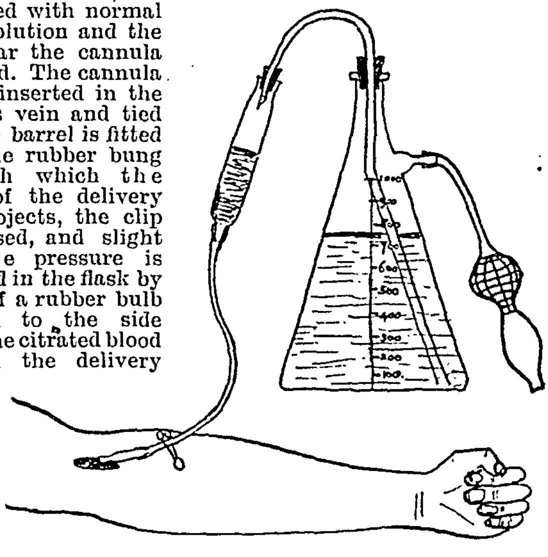

FIG. 3.—Showing air-lock in delivery tube of transfusion apparatus.

This technique is simple and straightforward at every stage, and can be easily demonstrated and learnt. Wide-bore needles (2 mm.) and a bevelled hone can be obtained from the General Surgical Company, Ltd., 147, Farringdon-road, London, E.C. The rest of the apparatus can be improvised in any laboratory.

FINANCIAL NEEDS OF DORSET HOSPITALS.—Dorset is the first county to have held a conference on the question of hospital requirements and the need for the continuance of the voluntary system. Lord Shaftesbury presided at the meeting, and it was stated that most of the institutions had an unfavourable balance. Sir Napier Burnett, formerly War Office hospital expert, stated that Dorset was not badly off as regards hospitals and the financial support accorded to them. Allusion was made to the fact that there were three hospitals "overlapping" at Weymouth, one of them having a deficit of £7000, and it was suggested that a conference of representatives of these three hospitals with the townspeople of Weymouth should be arranged and a scheme of coöperation formulated.

A STUDY OF CERTAIN EFFECTS OF OCCUPATION AND RACE ON THE HEALTH OF RECRUITS.

BY G. ROME HALL, M.D. DURH.,
FORMERLY DEPUTY MEDICAL COMMISSIONER, MINISTRY OF NATIONAL SERVICE.

UNTIL conscription was applied men were never examined in large quantities taken out of a specified area of the nation. Now statistics can be applied over a given area to all men between 18 and 42; to all classes of life and occupation; to those well or considered well, though with defects of minor degree; and to the really ill or decidedly defective. For example, there must be about 2 million men whose feet are more or less defective who could probably have been cured under a State Medical Service supervising their growth. Few people, again, have any idea as to the grave neglect of skin hygiene and its far-reaching effects. The surprisingly high categories in which clerks were placed shows that this occupation need not be unhealthy; while the absolute ill-health of the Russian Jews as a whole, and the close approximation of Jewish lads of 18 born abroad, but reared in Britain, to the British standard at the same age, proves there is nothing radically wrong with the physique of the Jewish race.

Heart Cases and Complexion—Racial Type.

But it is in the heart statistics that the examination of a block of the population should give really interesting results. The opportunity to collect them has never occurred before. The minor cases do not come for treatment, since it means losing wages, or they attend for some other ailment and resent a complete examination.

An analysis of 2500 heart cases was made from among my own cases, men I was asked to see by other examiners, and recruits who stated they had heart trouble. Of these 40 per cent. only have what is popularly known as heart disease, that is V.D.H., or excessive myocardial change. The illness of 50 per cent. was due to want of tone and minor causes, nearly all quite curable if the people concerned had been in a good financial position. In other words, many of these will drift into invalidism and national inefficiency for want of a fair chance. Another interesting feature is the proportion of dark to fair people who figure in this list. Of the 2500 heart cases, the proportion of dark to fair was as 3 to 2, and since among the other recruits examined there were two fair to every one dark, heart trouble would appear to be three times as common amongst the dark elements. As regards hyperthyroid action the dark are affected in the proportion of 10 to 1.

Feet, Genitalia, Teeth, Clothing, Body-weight.

The conditions of feet, genitalia, teeth, and clothing of 8000 recruits were all personally examined. The *feet* were defective in 23·8 per cent. I consider at least 18 per cent. of these feet defectives would have been curable had they been taken early enough to a medical man. The main causes operating in early life are badly fitting boots, with the great toe forced away from its proper line, and insufficient nourishment, with overstrain during adolescence. These cases usually became flat-footed.

The *teeth* were bad, in a state affecting health in 42·5 per cent. of these recruits. The standard adopted was: (1) A deficiency of teeth, either actually causing ill-health or bound to do so at middle age, or earlier, if dentures were not supplied. (2) The presence of large dentures, which was taken to imply a spell of ill-health, usually chronic sepsis, in the years before they were obtained. (3) Sepsis, with or without loss of teeth.

The *genitalia* were not normal in 14·6 per cent. of these 8000 recruits, but 80 per cent. of the defects were nothing more serious than a varicocele. Having noticed from practice among primitive negroes that quite 1 in 3 of the younger men had some definite defect, usually due to phimosis, soft chancre, or gonorrhœa, it occurred to me to take this opportunity of making a racial comparison.

Varicocele amongst our recruits, usually of quite a minor character, and in some cases disappearing with the colder weather, accounted for four abnormalities out of five. It occurred rarely amongst primitive negroes; my belief is that it is caused when the patient is in a state of general atonia by pressure of clothing, not directly, but by pressure on the right side, transmitted to the left cord.

It was found on local inquiry that two out of three of our population put on a vest or shirt (if no vest is used) once a week, usually on Sunday, and never take it off until the next Sunday. Medical men who have lived abroad in the tropics know the vital need of keeping the skin at its highest point of efficiency, as vital a need as to wash an infant daily. Neglect of skin hygiene in the tropics soon means acute disease; here it not only means "chills," rheumatic fibroses, pulmonary attacks as acute reminders of neglect, but an unhealthy dry condition, which I am convinced is responsible for nearly all the early arterio sclerosis not due to infections. Twenty years of industrial practice had made me convinced of the existence of these unhygienic habits, but the opportunity to get definite figures was absent until now.

In 70 per cent. of a group of 2618 men something abnormal was noticed in the throat. In most cases it was only congestion of the soft palate or of the pharynx, usually attributable to colds, smoking, or sepsis from the teeth sockets. But a considerable number had had nasal obstruction of one kind or other, and a definite group had lesions referable to middle ear disease through the Eustachian tube.

Of 10,000 consecutive recruits examined 105, or 1.0 per cent., were under 100 lb. (7 st. 2 lb.) in weight and 50, or 0.5 per cent., over 200 lb. (14 st. 4 lb.) in weight. There were put in C III or rejected 44, or 0.4 per cent., as under weight, and 11, or 0.1 per cent., as too heavy; 191, or 1.9 per cent., were over 6 feet high and 69, or 0.7 per cent., were under 5 feet high.

Classification in Relation to Occupation.

The classification of 1000 each of middle class men, clerks, craftsmen, open air workers not "craftsmen" gave the following results:—

—	Middle class	Clerks	Craftsmen	Open air workers
	Per cent.	Per cent.	Per cent.	Per cent.
A, B I, B II*	62.2	66.5	62.8	65.0
C I, C II†	7.9	12.5	19.7	18.9
C III, B III	20.7	15.1	9.2	8.1
Rejected	9.2	5.9	8.3	8.0

* Foreign service. † Garrison and labour at home.
‡ Sedentaries.

In the above table the following points stand out. The clerks show the best results, being highest in the foreign service group and lowest in rejections. But being taken in the Kingston on Thames area they were mostly of a special class, having wages high enough to be able to live outside of London.

The results of two half years examinations at Kingston are here shown. The first half year ending June, 1916, refers to a time when the recruits largely came up voluntarily, there being an undue ratio of middle class men. The second half year ended December, 1916, being principally a call up of the working classes, the best of whom had enlisted early in the war prior to conscription.

1st Half Year.	Total.	%	*2nd Half Year.*	Total.	%
General service	7 600	48.4	A	7,383	29.0
Field at home	1 715	10.9	B I	4 731	18.5
Garrison abroad	1 283	8.2	II	1 911	7.5
home	407	2.6	III	347	1.4
Labour	1 758	11.2	C I	3 698	14.5
Sedentary (B III and C III)	1 787	11.3	II	3 851	15.1
Rejected	1 159	4	III	2 165	8.4
			Deferred	469	1.8
			Rejected	978	3.8
	15 709			25,528	

Field service at home, garrison abroad and a certain part of labour ("fit for labour abroad") of the first half year nearly equalled B I, B II (garrison and labour abroad), practically the same standards.

Of 20,141 recruits, 6.2 per cent., or 1248, were referred to the ophthalmic surgeon. Of these he rejected 2.5 per cent., or 31. In three cases out of five the ophthalmic surgeon gave the same grade in eyesight as the recruit had already been placed in for general physique, and nearly all rejections were from the low physical grades.

Differential Results in Racial Grading.

The following table was made up of recruits of different nationalities, all of military age (18–42).

Grade.	British.		Russian Jews.		Italians.
I	48.4	70.1	14.2	30.4	17
II	21.7		16.2		18
III a	8.0	11.2	23.1	35.6	28
III b	3.2		12.5		12
III c	11.3		10.6		12
Deferred	7.4		4.4	23.4	7
Rejected			19.0		6

Since the figures refer to 15,709 British, 1000 Russian Jews, and only 100 Italians they are not strictly comparable, but may nevertheless be of interest. The British figures are taken from examinations in the Kingston district in the first half year of 1916 translated into the new gradings. Only a minority of the deferred would have been ultimately rejected. Since the best men had enlisted voluntarily the percentage of Grade I is much lower than it should be. Foreign service men amounted to 70 per cent. Of the Russian Jews nearly 80 per cent. were sedentaries in occupation. A consecutive 1000 were taken, of whom 30 per cent. were fit for fighting units in physique, but not in mentality; 40 per cent. were fit for auxiliary service and labour; 30 per cent. had no military value. There had been no prior call up of the Russian Jews. Only 100 Italians were taken. Those left in England mostly followed sedentary occupations; the younger men had gone.

Boys and Youths.—The following statistics refer to boys and 18 year old recruits:—

Grade.	Boys.	British 18 years.	Russian Jews 18 years.	Grade.	Boys.	British 18 years.	Russian Jews 18 years.
I	86.8	72.1	67.5	III c	—	1.2	—
II	10.3	15.1	16.2	Def.	—	3.1	2.5
III a	2.9	4.7	10.0	Rej.	—	2.5	3.8
III b	—	1.3	—				

Def., deferred. Rej., rejected.

The "boys" were 175 youths between 14 and 17 years 6 months, nearly all being over 16. The British youths of 18 comprised 2000 from 17½ years up to 19, the majority within three months of 18 on either side, but mostly over 18. The number in Grades I and II is only 10 per cent. under that of the boys so classified. I estimate that fair play in work, housing, and feeding would result in 85 per cent. being Grade I. Of Russian Jews of 18, 80 were taken over 17 and 6 months and under 19; no more could be obtained. These were all born in the Russian Ghettoes, nearly all of German extraction, and, brought to England in early life, had passed through our schools. Although handicapped, like their elders, by dwelling house and workshop conditions, the difference between their grading and that of the adult Jews is most marked. In fact, it closely approached that of British lads of the same age. This proves that there is nothing radically wrong with the race. Out of over 1700 Russian Jews examined only 11 were volunteers.

The reasons for rejections amongst the 2000 youths were as follows: poor physique, 3; deformities, 6; epilepsy, 3; mental deficiency, 6; pulmonary tuberculosis, 11; other tubercle, 4; valvular disease of heart, 8; eye disease, 3; hernia, 1; syphilis, 1; chronic meningitis, 1; eczema, 1; total, 51. Under an efficient State Medical Service, which includes proper feeding where necessary, 30 of the above invalids, or 3 out of 5, should not occur.

The Russian Jews and the Racial Incidence of Disease.

The differential analysis taken from a consecutive 1000 Russian Jews shows the following results:—

—	Total.	Rejected.	Rejections caused by tuberculosis.
Tailors and auxiliary trades	520	17·2 %	8·8 %
All others	480	20·7 %	8·9 %

The above were the first 1000 of the younger men. As time went on the results as to tubercle became worse, until the final figures showed 12·5 per cent. rejected. The Russian Jews suffering from healed and latent tubercle in workshop employ were passed for army workshops.

The following table shows the racial incidence of disease, as recorded on recruits' medical history sheet, also some other facts. The numbers affording this table are: British, 1100; Russian Jews, 1370; in consecutive groups.

—	British.	Russian Jews.	Remarks.
Illiterates	2 (0·2 %)	509 (37·1 %)	
Eyes, colour	353 (32·1 %) (not blue).	272 (20·0 %) (not brown).	
5 ft. 6 in. and under	494 (44·9 %)	1066 (77·8 %)	Normal English-man, 5 ft. 6 in.
Sedentary work ...	279 (25·3 %)	1030 (75·2 %)	
Over-stout	10 (0·9 %)	72 (5·3 %)	2 st. overweight.
Throat and nose ...	23 (2·1 %)	92 (6·6 %)	
Eyes, not defective sight	8 (0·7 %)	108 (7·9 %)	Jews, mostly trachoma.
Ear diseases	35 (3·2 %)	100 (7·3 %)	
Tubercle, active ...	6 (2·1) 0·5 %	155 (19·2) 11·3 %	Pulmonary. Any "closed" form.
" latent ...	18 1·6 %	108 7·9 %	
Lungs, other diseases	55 (5·0 %)	185 (13·5 %)	
Syphilis	12 (1·1 %)	27 (2·0 %)	
Gonorrhœa	7 (0·6 %)	28 (2·0 %)	
Epilepsy	4 (0·3 %)	20 (1·4 %)	
V.D.H.	23 (2·1 %)	18 (1·3 %)	Only disease markedly less for Jews.
Other cardiacs ...	111 (10·1 %)	186 (13·6 %)	Including "sedentary" heart.
Gastrics and enterites	24 (2·1 %)	62 (4·4 %)	
Feet, defective ...	134 (12·2 %)	338 (24·7 %)	Refers to low-grade feet only.
Other diseases ...	143 (13·0 %)	359 (26·2 %)	
Spinal	33 (3·0 %)	36 (2·6 %)	See notes following.
Injuries	57 (5·2 %)	45 (3·3 %)	

Some other diseases were recorded, but the results were nearly the same. Only in V.D.H. is the percentage of cases among the Jews markedly less than among the British; they showed very little true rheumatism, but a marked amount of fibrositis, due to septic, colonic, and gonorrhœal (?) infections, and to hilar tuberculosis.

Out of the 19·2 per cent. cases of tuberculosis 12·5 were rejected, the ordinary closed or latent case, if doing efficient work in a workshop, was posted to similar duties in the army.

Injuries were increased amongst the British by the call up of previously wounded men, and among the Russian Jews by self-inflicted injuries, ulcers, burns (electric), mutilated fingers, &c. The percentage of spinal cases among the Russians is probably small, because such cases would be unlikely to emigrate from Russia.

"Other diseases" do not include varicocele. The dietary of the Russian Jews was deficient in proteins, excessive in starch, probably only the cheaper, vitamine-free, fats were used. They were markedly wanting in "fibrosity"; they tended after 30 to pendulous abdomen when not neurasthenic.

EASTBOURNE WATER-SUPPLY.—The Eastbourne Corporation have decided to buy up the Eastbourne Waterworks Company for the sum of £408,365. The further purchase of West Dean and Friston farms, the natural watershed of the district, by the corporation will ensure an unlimited and perpetual supply of the purest water, and these farms are to be acquired as soon as possible.

ACTINOMYCOSIS OF THE CÆCUM,

WITH NOTES OF AN UNUSUAL CASE.

BY E. G. SLESINGER, *O.B.E.*, M.S., F.R.C.S.,
ASSISTANT SURGEON, GUY'S HOSPITAL.

ACTINOMYCOSIS, as it affects the various parts of the human body, has been very carefully studied since the original papers of Israel and Ponfick, and a good deal is known about the characteristics of the disease in its three main regional distributions—the face and neck, the lungs, and the alimentary canal. In the latter situation, however, it has become apparent of recent years that actinomycosis is by no means the rare disease that it was formerly thought to be, and the more constantly its possible presence is borne in mind by the surgeon the more frequently will it be recognised in its early stages, with correspondingly better results in its treatment.

Of the recognised cases of actinomycosis approximately 20 per cent. are intestinal, but it would appear, at the least, doubtful whether this represents anything like the real figure. One of the reasons of such a doubt is that many are cases of actinomycotic infection of the appendix, which are satisfactorily dealt with by the usual methods of appendicectomy, the true nature of the case only becoming apparent in the course of routine examination of the removed appendix if such is undertaken. Further, it is unlikely that such cases as that reported in the present paper are of any unusual degree of rarity, and yet I have been unable to find any report of a case of a similar nature in a fairly careful search of the literature of the last ten years.

The Mode of Infection.

In an excellent thesis on the subject in 1897 Hinglais stated that 60 per cent. of abdominal actinomycosis occurred in the appendico-cæcal region, and most writers since that time have given about the same figure. In regard to the method of infection in these abdominal cases there appear to be two main views, which, however, do not differ very greatly from each other. The first is that some infected foreign body, such, for example, as a grain of corn, lodges in the mucosa of the appendix or cæcum, and so carries the infection into the connective tissue planes, where alone it is pathological. A form of membranous surface infection of the mucous membrane has, however, been described, although its pathological significance appears somewhat doubtful. The second view of the mode of infection is that the actinomyces is a frequent normal inhabitant of the intestinal tract, an assumption which is based on the careful work of Dr. Wright, and the rôle of the foreign body is then thought to be merely that of causing the trauma which provides a portal of entry for the organism into the connective tissue planes. Here it spreads by a process of direct extension, for unlike tubercle and blastomyces, actinomyces does not spread by way of the lymphatics or blood stream, a fact which accounts for the extreme rarity of generalised infection in this condition.

Very varying opinions are held as to whether the cæcum or the appendix is the commonest primary site of infection. Kelly, Cope, and others maintain the latter, while Waring, who carefully reported seven cases, holds the former view. The appendicular theory rests mainly on the many cases where actinomyces has been found in appendices removed in the ordinary way, but there is no evidence to show that in many of these cases it represents anything more than the accidental presence of the organism. Cases undoubtedly do occur in which the appendix is definitely primarily affected by the disease, and in these it is noticeable that the base is the part nearly always attacked, in contradistinction to septic infections.

The Three Types of Infection.

Actinomycosis presents itself in the appendico-cæcal region in three different types. In the first and commonest type of case the patient insidiously develops a painless, gradually enlarging tumour in the right iliac fossa Such a case, if allowed to progress, ultimately forms abscesses and fistulæ, and more rarely even metastatic deposits in other parts of the body, particularly the liver This type of case has a grave prognosis, and is responsible for the sinister reputation the disease has in this respect The second type is more acute and begins with the symptoms of what is apparently an ordinary attack of fairly severe appendicitis This is operated on, and the appendix, gangrenous usually at the base, is removed, the nature of the infection not being generally recognised at the time In such a case the resulting sinus is slow in healing, and often during convalescence a secondary abscess forms and bursts through the wound, the nature of the case only becoming apparent at this period The third type seems to be much less common, and is represented by the case reported in this paper Here an actinomycotic patch formed in the cæcum and perforated, giving rise to a generalised peritonitis for which the patient was operated on

A peculiar feature of all types of abdominal actinomycosis, first pointed out by Lick and well marked in the present case, is the curious "yellow white facial appearance of these patients This colour is very like that so often seen in cases of ectopic gestation, and is quite distinct from the yellow of septic absorption or the dead white of a simple anæmia

Treatment

In regard to the treatment of these cases, the most important thing is early recognition of their nature In many instances this will depend on routine examinations of films and cultures The surgical treatment consists in opening and scraping sinuses, draining abscesses, or excising or invaginating actinomycotic patches Hydrogen peroxide is said to be a particularly valuable application Potassium iodide in large and increasing doses should be administered as soon as the infection is recognised, as much as 100 gr three times a day being necessary in some cases When these large doses are being administered, a careful watch must be kept for symptoms of iodism, and the other salts in the diet should be reduced Wild states that a good method with these large doses is to make a strong solution of the iodide in water and to give each dose in from 6 to 8 ounces of milk Several observers have reported good results from the use of vaccines

Case Report

The following case is unusual on account of the localised nature of the lesion and the onset with generalised peritonitis

L W, female aged 32 was admitted to Guy s Hospital for severe generalised abdominal pain Two years previously she had had a mild attack of pain in the right iliac fossa and since then has had abnormally painful periods The present attack began suddenly the day before admission with severe abdominal pain, worse in the right iliac fossa Bowels have acted normally

On admission, temperature 98 F, pulse 105 The patient had a curious yellow white colour and was very ill Abdomen tender and rigid especially over the appendix region Tongue dry and furred A diagnosis of perforated appendix was made and immediate operation advised and carried out On opening the abdomen a quantity of purulent fluid welled up from the pelvis and did not appear to be in any way shut off The cæcum and appendix were brought into the wound The appendix appeared normal but on the cæcum close to the base of the appendix there was a thickened patch about the size of a shilling with a perforation in the middle On scraping the margins of this patch yellow granules suggesting actinomycosis, were seen and direct films were made from it The appendix was removed, and the patch in the cæcum scraped and then invaginated The peritonitis was treated by the method described by Mr I J Steward several Carrel tubes being passed into the peritoneal cavity and a large exit tube left in the pelvis A continuous drip of normal saline was maintained through the Carrel tubes for three days all the tubes being then removed The patient was put on potassium iodide in doses which were quickly increased up to 50 gr three times a day Both the direct films and further films made from the peritoneal washings showed the presence of actinomyces The wound healed rapidly and the temperature which showed fluctuations up to 102° for the first 12 days speedily settled to normal When seen three months later the abdomen appeared normal the scar was firm and the patient in very good general health the change in her colour being particularly noticeable She is being kept under observation for some time, owing to the long intervals at which actinomycosis sometimes reasserts its presence

A CASE OF

PARATYPHOID "C" FEVER IN EAST AFRICA

BY R P GARROW, M D ABERD, D P H *

THE extended application of the method of hæmoculture in the diagnosis of P U O during the war has led to important additions to our knowledge of the bacillæmias causing continued fever Recent interesting contributions[1,2,3,4] to the literature of this subject place beyond doubt the existence of a fourth member of the enteric group of bacilli invading the blood stream and producing continued fever of the enteric type in man Although this "new germ of paratyphoid, as Hirschfeld calls it, differs from *Bacillus paratyphosus B* only in its immunity reactions, these differences are sufficiently important to entitle the organism to be named *Bacillus paratyphosus C*

Earlier workers[5,6] on this subject have reported bacillæmias due to organisms of anomalous character causing enteric like fever, but whether these bacilli are identical with *B para* C can only be decided if cultures have been kept for comparison It is possible that this same organism has been isolated many times in different parts of the world by different workers and its significance not appreciated *Bacillus paratyphosus C* has probably not an equal epidemiological importance with the three classical members of the group T, A, and B, as otherwise it would have attracted attention at an earlier date An organism corresponding in morphological, cultural, and serological characters with Hirschfeld s organism was isolated by hæmoculture from a case of continued fever at Port Amelia, Portuguese East Africa on Oct 28th, 1918, in course of routine blood culture for the diagnosis of many puzzling pyrexias met with in that country

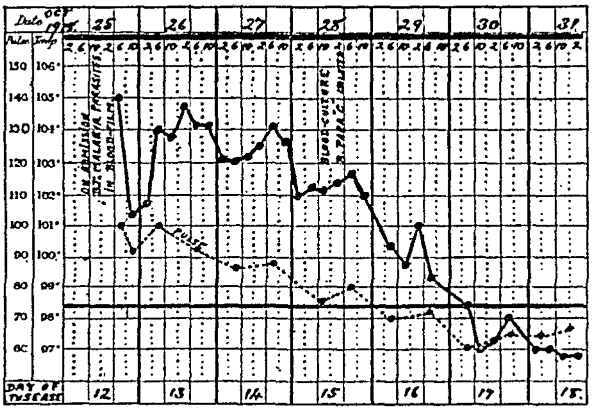
The rule was followed as far as circumstances would permit, of performing blood culture (5 to 10 c cm of blood from a vein sewn in 30 to 40 c cm of sterile ox bile) in every case of fever in which microscopic examination of blood films failed to show parasites, or in which the diagnosis was not otherwise clear The number of these cases was considerable, and they presented a great variety of temperature charts and clinical manifestations During 18 months' military service in East Africa in charge of a bacteriological laboratory I had the opportunity of blood culturing 313 cases of this kind Blood culture was advocated as the method which gives the most reliable evidence of active enteric infection, and its application was deliberately extended to the very large proportion of cases where there was little or no clinical evidence that the patient was suffering from enteric fever In doing this the object was not only to determine the extent to which the enteric group fevers prevailed amongst the troops but more especially to extend and amplify investigations which the writer had made during two years in the Mediterranean war area into the question of so called "atypical enteric fever

The case of paratyphoid C fever here recorded was the only case of this infection found in the course of these investigations It was a sporadic case, and in this respect differs from the cases of paratyphoid C fever reported from Macedonia and Mesopotamia,[7,8] in both of which areas the disease appears to have been more or less prevalent, if not actually epidemic.

History and Clinical Features.

The patient, a South African white, aged 42, who had never been out of Africa, was admitted to the 19th Stationary Hospital at Port Amelia on the twelfth day of his illness with a temperature of 105° F. The routine thick blood film showed benign tertian malaria parasites, and diagnosis was made accordingly. The temperature continued between *102 and 104° in spite of 30 gr. of quinine daily by mouth*, and on the fourteenth day of the illness with a temperature of 104°, no parasites were found on second examination of thick films. The medical officer in charge of the case, Captain C. Kelsall, West African Medical Staff, was not satisfied with the diagnosis of malaria alone, and requested a blood culture, which I did on the fifteenth day of the illness. 10 c.cm. of blood was withdrawn into a sterile syringe from a vein at the bend of the elbow, and discharged into 30 c.cm. of sterile ox-bile. The mixture was incubated at 37° C. for 24 hours and plated on Conradi medium. The result was a pure culture of the organism described below.

The patient displayed the five cardinal signs of active enteric infection of moderate severity: (1) Continued fever of remittent type ending by lysis. (See Chart.*) (2) A low pulse-temperature ratio. (See Chart.) (3) Characteristic toxæmia—dull, heavy, toxin-laden appearance with cheek-flush and heavily coated tongue. (4) A few rose spots on the epigastrium. (5) Palpable splenic enlargement (not of much diagnostic significance in this case on account of a history of many previous attacks of malaria).



The acute illness ended by a rapid lysis, and convalescence was uninterrupted. The attack was not in any way localised to one organ, and there were no lung signs beyond a few moist sounds at both bases.

The Organism Isolated from the Blood.

The organism recovered from the blood of this case on the penultimate day of pyrexia is a short motile Gram-negative cocco-bacillus with the cultural characters of *B. paratyphosus B*, but failing to agglutinate even in low dilutions of any typhoid or paratyphoid serum available for testing. (Lister Institute and Oxford sera, both active when tested with their homologous organisms.) Had the bacillus shown the cultural characters of *B. paratyphosus A*, failure to agglutinate in its homologous serum on first isolation would not have attracted special attention, as such an occurrence has been frequently recorded. But an inagglutinable *B. paratyphosus B* was unknown to me. These characters were confirmed by Major R. Semple, R.A.M.C., in charge of the bacteriological laboratory at Dar-es-Salaam, and by Dr. T. J. Mackie, professor of bacteriology in the University of Cape Town.

On my return to England I gave a culture of this organism to Major F. R. Coppinger, R.A.M.C., who found it to correspond closely with a strain of *B. paratyphosus C* from Macedonia. A subculture was sent for investigation to Dr. J. C. G. Ledingham at the Lister Institute, and a report has been received from Dr. H. Schütze, Lister Institute, stating that

"as a result of agglutination and absorption tests the organism has been found to belong to the group of Salmonella organisms called by Hirschfeld Paratyphoid 'C.' Serologically it more particularly corresponds with the Mesopotamian Paratyphoid 'C' called Baghdad 31."

The organism which on isolation was entirely inagglutinable in para. B serum now shows incomplete agglutination in all dilutions of B serum up to one-fourth titre.

Agglutination Reactions of the Patient.

Table I. gives the results of agglutination observations on the patient's serum. Formalised saline suspensions from agar slopes were incubated with progressive dilutions of serum in tubes in a water-bath at 55° C. for two hours, and read macroscopically, or with the aid of a small lens.

TABLE I.

Day of illness.	T.	A.	B.	C.	Day of illness.	T.	A.	B.	C.
15th ...	20 ...	0 ...	0 ...	—	28th ...	20 ...	0 ...	0 ...	80
19th ...	20 ...	0 ...	0 ...	160	45th ...	20 ...	0 ...	0 ...	40

The patient had been inoculated two years previously with two doses of T.A.B. vaccine prepared in South Africa. It was common to find inoculation agglutinins of very low titre or entirely absent in these cases. It will be noticed that tests carried out with the three classical enterica organisms gave a negative result. Tested against his own organism the result was positive.

Table II. gives the results of a series of tests with the serum of a case of paratyphoid B fever in the London Fever Hospital.

TABLE II.

Day of disease.	T.	A.	B.	C.	Day of disease.	T.	A.	B.	C.
9th ...	10 ...	0 ...	160 ...	0	25th ...	10 ...	0 ...	5120 ...	0
13th ...	10 ...	0 ...	1280 ...	0	31st ...	10 ...	0 ...	2560 ...	0
16th ...	10 ...	0 ...	2560 ...	0	33rd ...	10 ...	0 ...	1280 ...	0

This case of paratyphoid B fever, although it developed a high titre of para. B agglutinins, did not show any agglutinins for para. C.

Remarks.

1. This case illustrates the necessity for clinically checking laboratory results. Manson ("*Manual of Tropical Diseases*") warns the tropical practitioner against the common error of supposing that because a febrile patient has malaria parasites in his blood malaria is the only disease he is suffering from. Malaria frequently co-exists with other acute infections such as enteric fever. Indeed, the subjects of chronic malaria suffering from other acute infections sometimes show a few parasites in the peripheral blood, apparently without these being a factor in the production of pyrexia. In other words, pyrexia accompanied by malarial parasites in the peripheral blood does not necessarily spell acute malarial fever.

2. So far as I am aware, this is the only case of paratyphoid C fever reported from East Africa. Although the organism is more closely allied in its characters with *B. para. B*, it is interesting to note that, in its Eastern distribution, it corresponds more with *B. para. A*.

3. The case also illustrates the importance of hæmoculture as a method of investigation of continued fever. The results of *early* routine hæmoculture are incomparably superior in scientific value to any information that can be obtained by repeated examinations of the serum and excreta.

BOMBAY Corporation has adopted a scheme for the reorganisation of the health department staff in the branches of medicine, sanitation, and conservancy.

---

[*] Although the duration of pyrexia indicated on the accompanying chart is 16 days, the earlier part of the illness, of which there was no record except the patient's statement, may have been malaria only.

Medical Societies.

ROYAL SOCIETY OF MEDICINE

SECTION FOR THE STUDY OF DISEASE IN CHILDREN

EXHIBITION OF CASES AND SPECIMENS

A MEETING of this section of the Royal Society of Medicine was held on May 28th, Mr J P LOCKHART MUMMERY, the President, being in the chair

Dislocation of the Thumb —Oxycephaly

Mr B WHITCHURCH HOWELL showed a case of Dislocation of the Thumb in an infant The acute flexion of the terminal phalanx caused it to resemble congenital contraction, a condition with which it might easily have been confused had no history of the accident been available

Dr THEODORE THOMPSON showed a case of Oxycephaly in a child 1 year old The child showed an extreme degree of this deformity, the eyes being very protuberant and the vertex of the skull very high The occiput was but little developed An especially interesting feature was that the early age of the infant permitted an increased intracranial pressure to be recognisable readily The anterior fontanelle was widely open and bulging and the posterior fontanelle was also open The frontal bones were separate No other deformity was present, and the intelligence was good

Congenital Heart Disease

Mr D H PATERSON showed two specimens of Congenital Heart Disease

CASE 1 was that of a male baby, aged 10 months who had been admitted to hospital acutely ill with general pulmonary catarrh accompanied by high remittent fever Contrary to the rule his dyspnœa had been less in the completely supine position than when he was propped up The pulse was over 160 and often uncountable There was no definite bruit Death occurred after three days Before admission to hospital he had been feverish for a day or two Blueness had never been noticed but there had been previous attacks of breathlessness Post mortem the lungs were congested but there was no evidence of pneumonia The heart weighed 2 ounces 14 drachms Immediately below the aortic cusps there was a hole in the interventricular septum The aortic pulmonary, and mitral valves were all large distorted, and fleshy, but the endothelium was glistening and showed no evidence of inflammation an observation which was corroborated by microscopical examination Both the right and left ventricles were hypertrophied the left more than the right The ductus arteriosus was closed

CASE 2 was that of a male infant aged 8 weeks admitted to hospital for cough and dyspnœa of one day's duration accompanied by moist sounds in the lungs The dyspnœa was urgent and it was found necessary to support the chest and let the head fall well back to enable the child to breathe The respirations were sometimes rhythmical The child was extremely pale No cardiac murmur was heard Death occurred next day Post mortem the lungs were merely congested The heart was transversely placed within the thorax and weighed 2 ounces 6 drachms The right auricle was distended and thin walled, and the left auricle small and rudimentary Communicating between the two was a patent foramen ovale admitting the tip of the little finger In the floor of the left auricle lay a completely stenosed mitral orifice The right auriculo ventricular valve consisted of two cusps and the corresponding orifice led into a large thick walled chamber from which both the aorta and the pulmonary artery proceeded The valves of these vessels were well formed Below the origin of the pulmonary artery was a dilated space, the bulbus cordis, which according to Professor Keith corresponded *developmentally to the third* ventricle of the fish The ductus arteriosus was not patent

A Case for Diagnosis

Dr E A COCKAYNE showed a case for diagnosis, probably one of Congenital Syphilis

The boy aged 9½ years, was undersized and mentally backward His arms and legs were very long in proportion to his trunk the distance from the symphysis pubis to the ground being only 1½ in less than from the symphysis pubis to the vertex The limbs were very slender and the feet and hands very narrow but not longer than normal Radiograms showed marked osteitis of the whole of both femora and very slight osteitis of the tibia and fibula Both humeri were thickened and probably the seat of osteitis There were general muscular weakness lordosis and flat feet The testicles were very small There were no other stigmata of congenital syphilis the Wassermann reaction was negative and the family history was good

---

MONTPELLIER SOCIÉTÉ DES SCIENCES MÉDICALES ET BIOLOGIQUES

AT a recent meeting of this society M DE ROUVILLE and M J COHEN reported a case of a large Sessile Anterior Cervical Fibroid developing intra ligamentary and also between the layers of the pelvic mesocolon The woman aged 40 presented as chief symptoms slight menorrhagia with lumbo abdominal pains Difficulty was experienced in opening the abdomen on account of adhesions between the peritoneum and anterior surface of the tumour The uterus contained fibroids and was removed subtotally after enucleation of the tumour from between the two layers of the left broad ligament and the pelvic mesocolon The bladder was accidentally opened during the operation the opening was closed and the abdomen closed without drainage A self retaining catheter was placed in the bladder An excellent result followed The authors remarked especially upon the new connexions contracted by the bladder in the case of anterior cervical fibroids which render it easily wounded at *operation*

At another meeting M SAPIOX and M TZELEPOGLOU described a case of a Double Parovarian Cyst with a long twisted pedicle, the ovary and the tube participating in the torsion The cyst arose on the left side and ascended nearly to the liver on the right The pedicle had undergone three *complete turns Its wall* presented numerous ecchymoses but the fluid contents of the cyst were quite clear Histological examination of the cyst wall showed that the hæmorrhage was limited between two lamellæ of fibrous tissue

M GRYNFELTT contributed a paper on the Histology of a Galactocele The case presented an interesting feature from a *clinical* point of view—its origin was found *to be* due to a bite of a horse Contrary to what is usually found the author did not find any lesion permitting the placing of the tumour amongst the fibro adenomas The wall surrounding the liquid collection was a fibrous membrane of new formation As in all the cases described there are inflammatory *lesions present without one being able to consider them as* chronic abscesses of the breast for the contents are not those of an abscess A study of the contents of the galactocele enabled the speaker to establish the following conclusions (*a*) Numerous granular bodies closely resembling colostrum corpuscles are present in the fluid (*b*) These *granular bodies result from the conversion of* white spherules whose cytoplasm becomes charged with fat globules (*c*) These *granular bodies* act *as* true glandular elements and *not as* scavengers *in* removing mechanically the contents of the collection (*d*) It is this process which explains the cases of spontaneous cure of this affection but *it is not the only factor, for the* wall *of the* galactocele proliferates into the interior of the *milky mass* and tends to obliterate the cavity

---

MEDICO PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND —The ordinary quarterly meeting of this association was held on May 20th at the rooms of the Royal Society of Medicine under the presidency of Dr Bedford Pierce when the first Maudsley lecture under the bequest of the late Dr Henry Maudsley, was delivered by Sir James Crichton Browne who in a comprehensive essay dwelt on the modern combination of laboratory and clinical work and the necessity of founding mental hospitals He concluded with references to shell shock and general war neuroses The address was much appreciated by those present, and a vote of thanks to the lecturer proposed by the President and seconded by Sir George Savage was carried with enthusiasm The sequel to the address will be published in two parts the first part appearing in our present issue (p 1248)

SOCIETY OF MEDICAL OFFICERS OF HEALTH FORMATION OF A TUBERCULOSIS GROUP —A meeting was held at 1 Upper Montague street London, W C on May 28th for the purpose of forming a Tuberculosis Group within the society All tuberculosis officers and others interested in the Group were asked to attend Dr J N Kay Menzies presided, and after welcoming those present, spoke in favour of the proposal before the meeting After some discussion, in which Drs Halliday Sutherland G Jessel Hyslop Thomson and H A Ellis took part Dr Thomson moved that the Group be formed and that Dr I G Caley be made secretary Dr A Ashkenny seconded and the resolution was carried A committee, consisting of Drs Ellis Caley, J Sorley, F Stanley Tinker, and M Macdonald was appointed to draw up rules and it is suggested that the first meeting of the Group should be held in July

Reviews and Notices of Books.

1. La Fatigue de l'Appareil Visuel chez les Ouvriers Mineurs.

Par le Dr. M. **Stassen**. Liége: H. Villant-Carmaune. 1914–1919. Pp. 234.

2. Miners' Nystagmus.

By **Frederick L. Hoffman**. Washington: Government Printing Office. 1916.

1. Dr. M. Stassen's book will rank with that of Dr. Lister Llewellyn (published in 1912), among the chief authorities on miners' nystagmus. As to the main cause of the disease, the two are in entire agreement, and, indeed, the evidence is overwhelming that the defective lighting of coal-mines is, in the main responsible. Dr. Stassen puts it in this way: *the overwork imposed on the visual apparatus of the coal-miner, obliged to work continuously in partial darkness, produces a nervous syndrome characterised by incoördination and exaggeration of the visual reflexes.* The clinical symptoms of this syndrome may vary, but they are all the results of accumulated fatigue. Hemeralopia, retinal asthenopia, insufficiency of convergence, blepharospasm, and other symptoms which may precede or accompany nystagmus are all alike due to visual fatigue from work in defective light.

After an historical chapter, in which the literature since 1861 is briefly summarised (and in which, by the way, the names of English authorities are sadly mauled about), and another in which the physiological conditions to which the coal-miner is subjected are described, various statistics and clinical observations are detailed, all tending to the same conclusion as to the causation of the disease. There are, no doubt, other contributory factors in many cases, and it stands to reason that since only a minority of the miners who work under similar conditions are attacked, the nervous constitution of the patient is a matter of primary importance. That the nystagmus of miners, however, has very little in common with the labyrinthine variety is suggested by an interesting chapter, in which it is shown how the oscillations of the eyeball which occur in the two forms of the disease may be analysed by means of the nystagmograph of Buys. In miners' nystagmus an oscillation of the eyeball occurs in which the movements to and fro are symmetrically timed, whereas in the case of labyrinthine nystagmus the movements comprise a series of jerks consisting of a rapid movement in one direction and a slow recovery. It is possible for the two diseases to coincide in one patient, but in that case the result is not a combination of the two types of movement, but the appearance of now one and now the other type of nystagmus, according to the conditions of the moment.

It is when we come to a description of the practical measures to be taken for improving the lighting of the coal-mines that we find the information contained in this book insufficient. Electric lamps had only been introduced in a few Belgian mines shortly before the war, and although these are recommended by the author he points out the disadvantage they have compared with the safety-lamp in failing to warn the miner of the presence of fire-damp; it has even been found necessary in certain dangerous mines to provide the miner with an oil safety-lamp in addition, thus adding both to the weight and the expense. Further, to avoid dazzle the author recommends that the electric lamp should be partially frosted.

2. The American Bureau of Mines has printed this pamphlet with the avowed object of disseminating information. It is a compilation from various sources, chiefly English, but also Belgian and German, and it is disappointing to find that there are practically no American investigations on the subject. There is only one report derived from an American source, compiled in January, 1911, by the Illinois Commission on Occupational Diseases. In this the rarity of miners' nystagmus is remarked. Out of 500 pick-men examined not a single case was found. The report inclines to the older view that the disease is caused by a constrained position of the body with the eyes directed upwards, a view of the disease which the more recent investigators in this country are unanimous in rejecting.

Cunningham's Manual of Practical Anatomy.

Vols. I. (Limbs) and II. (Thorax and Abdomen). Seventh edition, revised by **Arthur Robinson**. London: Henry Frowde and Hodder and Stoughton. 1920. Pp. 451 and 524. 12*s*. 6*d*. per vol.

The addition of extra matter and a considerable number of new illustrations makes it necessary that "small Cunningham" should appear in three volumes in this edition, and these are the first two numbers of the new issue. The work, of course, has long passed the era of criticism, and is firmly established at the head of all dissecting manuals. These volumes have been revised in many ways; the directions for dissecting are more prominent, a good deal of editing of the text has been undertaken, and many new figures of dissections and sections have been introduced, with a large number of radiographs. All concerned with the production have reason to be proud of the two beautiful volumes so far issued in the edition. We notice one or two minor misprints in the second volume: thus, in Fig. 82, the urethra is termed ureter, the round ligament of the liver seems to run a curious course with reference to the inferior mesenteric vein in Fig. 162, and in Fig. 205 the lower label of the levator ani appears to indicate the internal sphincter. The Basle nomenclature is used throughout, with occasional references to the English terminology.

Sanitation for Public Health Nurses.

By **Hibbert Winslow Hill**, M.D., D.P.H., Professor of Public Health, Western University. London and New York: Macmillan Company. 1919. Pp. 209. 7*s*.

"This book was written to give public health nurses a concise view of the fundamentals of modern public health as it is to-day," but after this sentence in the preface the nurses in question appear not to have bulked more largely in the mental audience of the author than others of the public who are interested in preventive medicine. The work is an essay on practical epidemiology, with a popular description of those infectious diseases which are most common in America, with chapters on food, flies, cleanliness, ventilation, and vital statistics. It is modern in its contents and original in some of its methods of teaching.

Many parts of the book will appeal more to that section of the medical profession which is interested in the ætiology and prevention of infectious diseases than to nurses and health visitors, as we call "public health nurses." The latter can hardly be expected to be "up" in the subjects of paratyphoid fever and anaphylaxis, nor in "Duke's disease" which Dr. Hill disposes of by classifying rötheln into "scarlatinoid German measles" and "measly German measles." A much more severe type of scarlet fever is described than that which is now common in this country. The views expressed are, on the whole, sound, and there are several interesting observations noted—e.g., that the aural discharge of measles does not appear to be infectious.

The chapter on cleanliness may be specially commended to those who aim at the chastening of health faddists. Its aim is largely to show that infectious disease cannot be avoided by cleanliness, in the general sense of the word, but only by such scientific and coördinated measures as prevent the inroad of the special forms of foreign matter which convey the materies morbi of these diseases. This chapter may be commended to all nurses, while those nurses and health visitors who have been sufficiently educated to appreciate the terms used will find the whole book worth reading. The chapter on vital statistics contains specimens of propaganda child-welfare leaflets, which should be found useful in schools for mothers. Each chapter concludes with a summary—a practice which might with advantage be more generally adopted.

TAYLOR'S PRINCIPLES AND PRACTICE OF MEDICAL JURISPRUDENCE.

Seventh edition. Edited, revised, and brought up to date by FRED. J. SMITH, M.A., M.D. Oxon., F.R.C.P., F.R.C.S., Physician to, and Lecturer on Medical Jurisprudence at, the London Hospital. London: J. and A. Churchill. 1920. Vol. I., pp. 940; Vol. II., pp. 952. £3 3*s*.

THE nature and scope of this work are too well known to require any introduction to our readers. In his time the late Dr. Alfred Swaine Taylor was undoubtedly the leading English medical jurist and toxicologist, and several editions of his treatise appeared rapidly. The fifth and sixth issues were ably edited by the late Dr. F. J. Smith, as well as the seventh, whose two volumes form an excellent and exhaustive account of medical jurisprudence. They will be found especially useful for reference; the very large number of illustrative cases and legal decisions which they contain render the work valuable both to barristers and medical men in dealing with medico-legal problems. Many changes are to be found in the present edition, and in the preface the editor acknowledges the unstinted assistance given him by Dr. W. Bulloch, to whom are due the references which will be found at the end of nearly every section of the work. These are especially numerous in the section of toxicology, where new information on various poisonous substances has been added and numerous rare cases of tragedy and crime have been recorded. The section on lunacy has been entirely recast and brought up to date. The Mental Deficiency Act has received notice, as have also the resolutions of the Pharmaceutical Society on the Poison Schedule.

During recent years the Workmen's Compensation Act has added greatly to the work of the Law Courts, and it is most advisable that medical practitioners should make themselves acquainted with the subject. The problems are well set out which may present themselves when claims are made under the Act, and many cases and decisions are given which will serve as guides in the consideration of any particular case. The question "What is an accident?" has now assumed complexities and proportions totally unthought of years ago, and the wording of some of the clauses of the Act is confusing. The observations on this subject are well worth perusal. Dr. Smith's large experience as a medical referee to the Home Office gave him opportunities of seeing the practical working of the Act, and the cases recorded well exemplify the difficult and complicated positions which present themselves. The relation of antecedent disease to "accident" is dealt with at length; this matter is intimately connected with medical evidence and often gives rise to differences of opinion. We entirely agree with the dictum that in all fatal cases an autopsy should be held; the medical witnesses may then explain the bearing of these facts on the fatal event and leave to the law the decision as to the adjustment of compensation. The arrangement of the index calls for special approval. The illustrative cases are classified under headings, so that when dealing, say, with a case of gunshot wound similar cases can at once be consulted. This makes for great saving of time and removes risks of error.

We can once more speak in the highest terms of Taylor's Jurisprudence, both as a work of reference and as a book to be studied for the higher examinations.

A MEDICAL HANDBOOK.

For the Use of Practitioners and Students. Fifth edition. By R. S. AITCHISON, M.D., F.R.C.P. Edin., late Medical Officer, Out-patients' Department, Royal Infirmary, Edinburgh. London: Charles Griffin and Co. 1920. Pp. 390. 10*s*. 6*d*.

THIS little handbook, which has now reached a fifth edition, provides an excellent clinical summary of medical disorders. The book is intended to form a vade-mecum which the busy practitioner can read through rapidly. The classification of diseases is entirely clinical, this arrangement having been adopted with a view to increasing the value of the book in the practical diagnosis of disease. The author's personal experience finds more ample expression than is commonly the rule, while the references are not confined to recent advances in medical knowledge, but preserve much that is reminiscent of former wisdom. "General Data Useful for Reference" are collected together towards the end of the book, and the subjects dealt with cover a wide field. Here will be found a classification of skin diseases, rules for the management of infants, incubation periods, notes on certifying the insane, a classification of poisons according to the treatment required, signs of approaching death, &c. Post-mortem examination and prescribing are the subjects of yet other chapters, and an appendix deals with such subjects as test meals and Widal's reaction. Well-established drugs rather than the newer remedies find a place in the sections devoted to treatment, and a useful collection of prescriptions in general use has been appended. This thoroughly useful book is illustrated by upwards of 40 figures.

THE SEXUAL DISABILITIES OF MAN.

Their Treatment and Prevention. Fourth edition. By ARTHUR COOPER, M.R.C.S., L.R.C.P. *London*: H. K. Lewis and Co. 1920. Pp. 266. 7*s*. 6*d*.

THE value of this book, a useful treatise in its earlier form, has been enhanced by the addition of two new chapters, carefully and moderately written, on hygiene and continence. The first of these chapters is summarised in the author's rule that "no two persons of any age or sex should sleep together in the same bed." The application of this rule to husband and wife in particular is justified by a wise and detailed discussion of marital needs. It is to be regretted that in the chapter on continence the importance of early marriage is not definitely insisted on, for this is the practical lesson which shapes itself insistently in our mind after reading Mr. Cooper's argument. In youth continence is both possible and desirable, from the psychological as well as from the physiological point of view; for, as Montaigne puts it: "Il n'y a n'y continence n'y vertu, s'il n'y a de l'effort au contraire." But, as Mr. Cooper frankly says, the sexual appetite is natural, and while it may be advantageously controlled it cannot be permanently repressed without damage to the normal individual. For this reason as well as for many others —the control of venereal disease among them—a State subsidy in aid of early marriage might be a blessing to society.

A postscript is added on the relation of warfare to sexuality. It consists of quotations from various authors. Two conclusions appear. In the first place that the dominant appeal to the instinct of self-preservation relegates the sex instinct to a place of secondary importance under combatant conditions. Secondly, that the unnatural grouping of healthy males in large bodies isolated from the rest of the community tends to sexual perversion. These facts are now fairly well recognised, and scarcely needed further emphasis.

FACIAL NEURALGIA AND ITS TREATMENT.

With Especial Reference to the Surgery of the Fifth Nerve and the Gasserian Ganglion. By J. HUTCHINSON, F.R.C.S., Surgeon to the London Hospital. London: John Bale, Sons, and Danielsson. 1919. 37 figures. Pp. 216. 15*s*. net.

THIS monograph is an enlarged revision of the essay which received the Jacksonian prize at the Royal College of Surgeons of England in 1915. The book opens with an account, well illustrated with drawings from dissections, of the surgical anatomy of the fifth nerve. The causes and different forms of facial neuralgia are then passed in review, and the minor neuralgias are clearly distinguished from the epileptiform variety, the term the author uses to denote tic douloureux. The greater part of the book is devoted to a consideration of the symptoms, course, pathology, and treatment of the epileptiform type. Before advising excision of the Gasserian ganglion the surgeon is warned that he must ascertain that his patient is the subject of true epileptiform neuralgia and of nothing, else, if the result is not to prove disappointing. Above all must he exclude cases simulating tic douloureux in hysterical or neurasthenic subjects. By the modified operation which Mr. Hutchinson advocates—that is, by sparing that part of the ganglion concerned with the first division of the fifth nerve—all fear of subsequent damage to the patient's eye can be avoided. The temporal route of approach is the one recommended, and as the whole of the skin flap is made within the area of the scalp the scar is subsequently concealed by growth of the hair. It is a surprising fact that patients suffering from tic douloureux will endure its tortures for five or ten years rather than seek relief by an operation, which in competent hands, performed by the method set out in this monograph, is mostly free from risk to life or eyesight.

A critical account of the treatment by alcohol injections is given, and a method adopted by the writer of approaching the superior maxillary division of the nerve through the orbit is described. The conclusion arrived at is that sooner or later with treatment by alcohol injections recurrence of the neuralgia occurs. A short account is given of neurectomy of the second and third divisions of the nerve. Resection of the superior maxillary division has an advantage over removal of the Gasserian ganglion in that the motor fibres are not involved, hence the masticatory muscles retain their power and there is an entire absence of deformity of any kind; but as a curative operation neurectomy is inferior and recurrence of pain sometimes compels a resort at a later date to removal of the ganglion. An extensive bibliography brings an excellent monograph to a close.

THE TOPOGRAPHICAL ANATOMY OF THE LIMBS OF THE HORSE.

By O. CHARNOCK BRADLEY, M.D., D.Sc., M.R.C.V.S. Edinburgh: W. Green and Son. 1920. Pp. 172. 21s. net.

THIS is a manual for veterinary students who are dissecting the horse's limbs, and is a clear and carefully written guide for their researches. Perhaps in future editions a little more stress might be laid with advantage on the relations of the structures described, and references in the text to the figures, when appropriate, would be of some value to the learner. These figures are an outstanding feature of the book, and one would like to see full use made of them. The author does not confine himself to bare description, but every now and then goes shortly into morphological points and thereby enhances considerably the interest of his subject. The derivation of anatomical terms is treated in footnotes by Dr. E. B. Jamieson. This is a custom which has fallen into disuse in works on human anatomy, but is one that might be revived with advantage in these days of non-classical education in order that students may learn, in Principal Bradley's words, that "terms are more than mere collections of letters." The author uses the Basle nomenclature, but apparently could not bring himself to the point of using the names which that terminology inflicts on the carpal bones.

A JUNIOR COURSE OF PRACTICAL ZOOLOGY.

Ninth edition. By the late A. MILNES MARSHALL and the late C. HERBERT HURST. Revised by F. W. GAMBLE, D.Sc., F.R.S. London: John Murray. 1920. Pp. 517. 12s.

Milnes Marshall had a wonderful vivacity, which is shown in the practical book still bearing his name. The eighth edition appeared quite recently, and sufficient time has not elapsed since its publication for Professor Gamble to find many changes necessary. A new account of the tapeworm has been added, based upon a description of *Dipylidium caninum*, the tapeworm most commonly found in the dog. There has also been some revision in the nomenclature of the vertebrate kidney. It is a pleasure to notice that instead of increasing the price of the book the publishers have actually been able to reduce it.

PRACTICAL HISTOLOGY.

Third edition. By J. N. LANGLEY, Sc.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge. Cambridge: W. Heffer and Sons, Ltd. 1920. Pp. 320. 10s. 6d.

AS physiology is concerned with the functions of an organ in its aspect as the sum of the functions of its microscopical constituents, the author thinks the custom in British universities for histology to form part of the course of instruction in physiology is indubitably the best, at least so far as the teaching of elementary students is concerned. The present work was already so good, the outcome of extensive experience in the Cambridge School, that the reader would hardly expect many changes. Still, a number of changes have been made, including recent improvements in methods and alterations in nomenclature. The author is of opinion that whilst some knowledge of method is necessary, it is more important for an elementary student to be able to understand what is shown by the specimens than to be able to make them. There is a fair amount of small type giving notes for advanced students. The directions are clear, precise, and definite, and deal partly with the art of making the preparations, partly with descriptions of the objects to be recognised and identified in each section. As to section-cutting, the only instrument figured is the rocking microtome of the Cambridge School. As in previous editions, there are no illustrations of the sections in the text, which is descriptive only, the student being thereby encouraged to make a drawing of what he sees. The book is an admirable compendium, compressed into 36 lessons, of what a medical student ought to know of histology, and if he makes good use of the "demonstrations" his knowledge will be greatly enlarged and extended.

JOURNALS.

The Journal of Industrial Welfare. Price 6d. monthly. Published by the Industrial Welfare Society, Sanctuary House, Tothill-street, S.W.—Industry, by grouping together larger or smaller numbers of the community in the common interest of production, provides social machinery which may be used in a variety of ways. In our own columns we have from time to time dwelt upon the way in which industrial organisation is of value for developing the science of industrial hygiene, and also on the importance to this science of social knowledge. There are two sides to the work, a medical side and a social side, complementary and necessary the one to the other. Among contemporary publications *The Journal of Industrial Hygiene* may lay claim to represent the medical side, and we note its editors do not neglect the social aspect. We have been watching with interest the appearance of another periodical, the *Journal of Industrial Welfare*, which should claim to represent the social side; it is well printed and well illustrated. But we must confess to a feeling of disappointment with its contents; accounts of sports, of the performances of theatrical troupes, pictures of canteens and of gymnasiums, a little safety-first and hints at first-aid, made useful propaganda a few years ago. To-day industry wants something more definite, and so does the medical profession; the supporters of this industrial journal are for the most part large employers of labour; and might be expected to issue information based upon scientific data rather than sketchy allusions to welfare schemes. Masters and men are to-day hard-headed folk; they like to have facts plainly set forth. What do welfare and health schemes cost? What benefits result to those concerned? When a well-intentioned employer starts a scheme the workers ask, "Where is the snag?" If the men propose it the employers ask, "Where do we come in?" We hope that this new journal, by anticipating such obvious questions, will yet see its way to taking up the position it should. We all need real information by industrial economists, setting forth the economic value of welfare in reducing labour turnover, in lessening lost time, in settling personal grievances, in increasing efficiency, and in promoting good fellowship. These things may happen, but it is for those who claim their truth to state the evidence, and to show as clearly as it can be shown that industrial welfare is mutually beneficial, that here neither capital nor labour can benefit at the expense of the other, and that neither can benefit without the other also benefiting.

THE late Mr. H. G. Turner, of Staplegrove, Taunton, has bequeathed £1000 to the Taunton and Somerset Hospital.

THE LANCET.

LONDON: SATURDAY, JUNE 5, 1920.

The Outlook in Medicine and Dentistry.

IN his Presidential Address at the opening of the summer session of the General Council of Medical Education and Registration, Sir DONALD MACALISTER made the customary survey of the changes that had taken place since the last session and indicated the problems arising for present consideration. There will be but little penal business to be dealt with, and though important educational matters will be discussed the President saw no reason to anticipate a long session. In chronicling the transference to the Ministry of Health of the duties hitherto performed by the Secretary of State with regard to the Anatomy Acts, Sir DONALD MACALISTER expressed the hope that the new arrangement would lead to "much-needed improvements in the provision made for the practical teaching of anatomy and surgery." Most of the 3420 new students placed on the Register in 1919 will find their way to the dissecting-room this autumn, and their extraordinary number —more than double that of 1914, and exceeding by 1000 the previous record annual entry—makes the provision of adequate material a most urgent problem. Students cannot acquire a satisfactory knowledge of anatomy in the proportion of 20 or 30 to one subject. The relative ease—depending mainly on the persuasiveness of the resident medical officers of the various institutions—with which pathological human organs can be obtained for purposes of investigation and demonstration must cause envy among those whose essential teaching material consists of normal skeletal, muscular, and nervous tissues in situ. Not the most skilful special pleading convinces the general public—in whom the demands of the anatomists still arouse horror, even though biological knowledge is becoming more general—that the practice of dissection is likely to lead directly to the relief of human suffering. It becomes, therefore, the business of an enlightened department of the State to see that the needs of the anatomical school are met in a sympathetic spirit.

The position as regards qualified recruits to the profession is not so unsatisfactory as might have been feared, since the Medical Register in 1919 was enriched by the names of 450 practitioners on the Colonial and Foreign lists. The proportion of women to men is still on the increase, and Sir DONALD MACALISTER had a word of warning for those who are too optimistic about the professional chances of recently qualified women in the immediate future. However, there still appears to be a need for students of both sexes in the sister profession—hitherto something of a step-sister in popularity—of dentistry. The addition of only 128 dentists, as against 1322 doctors, to the Register in 1919 seems disproportionately small, especially since the dentist is acquiring more and more importance as a valuable ally in the cause of preventive medicine. It is true that the ratio, roughly 2 to 1, of the entry of medical students in the two years 1919 and 1914 is almost exactly reflected in the Dental Students Register, but the extension of conservative dentistry to the masses is leading to a relative increase in the demand for dentists and following the promised Bills dealing with dental registration and the general improvement of dental services, the numbers of doctors and dentists should tend to approximate. Even if they devoted their whole time to school work the existing dentists could not cope with the needs of the 5,750,000 school children while neglecting the rest of the population. And unfortunately evidence seems to be accumulating that the British need for good dentistry, preventive and curative, has been allowed by popular ignorance and slackness to become a national reproach.

Intending students of medicine and dentistry, and those interested in their careers, would do well to study the figures given by the President of the General Medical Council. He calls attention to the overcrowding in the medical schools and suggests that the authorities concerned would welcome a reduction in the entry until the capacity of the profession to absorb so many new recruits is established. The considered words of Sir DONALD MACALISTER should carry weight, for no one who has followed his presidential addresses to the Council can fail to have been impressed by the accuracy of his forecasts and the care which he has shown in guiding the deliberations of the body whose duty it is to maintain our profession at a high standard to meet the public need.

◆

A Quantitative Test in Pulmonary Tuberculosis.

THE value of the investigations carried out by Professor G. DREYER and Dr. L. S. T. BURRELL, whose paper we publish in this issue, is greater than a casual perusal might suggest. Not only do they describe a quantitative test of the severity and extent of pulmonary tuberculosis and of its reaction to treatment, but they also set up an anthropometric standard by which, it may be hoped, the potentially tuberculous, and not merely the tuberculous, can be judged. Most of their investigations concern definitely tuberculous or healthy persons. To distinguish between these two classes is easy enough without the aid of elaborate tests. But there is a large intermediate class consisting of the ante-tuberculous, whose lowered vitality is the expression of heredity and of that ill-defined condition labelled diathesis, and the tuberculous, whose disease is still clinically latent. To what extent can this anthropometric standard help us at once to pick out the candidate for consumption ten years or more hence? The plan, originated by the Framingham Community Health and Tuberculosis Demonstration in the U.S.A., of making wholesale health surveys, promises to be adopted in many other parts of the world, and the time may not be far off when respectable citizens will enjoy the benefits of analyses and examinations which have hitherto been inflicted almost exclusively on criminals. When that time comes, what will be the tests by which the prospective consumptive will be singled out? v. PIRQUET'S and the other tuberculin tests leave much to be desired; they have served a useful purpose in referring the problem of tuberculosis back to infection in early childhood, but they are of little diagnostic and prognostic help in the period—often measured by decades—between infection and the outbreak of tuberculosis. Is the anthropometric standard sufficiently free from sources of error to distinguish not only between classes A, B, and C, but also between class A, and what we would call class A (2)? Professor DREYER and Dr. BURRELL do not at present claim to have evolved a test of critical and decisive value in ante-tuberculous cases, but in establishing the importance of their test in relation to well-defined disease they are building a solid foundation on which more ambitious structures may be reared.

A line of research which might yield instructive data would be a comparison of the vital capacity constants in the first- and the later-born. Can the comparatively great susceptibility of the first-born to pulmonary tuberculosis, as proved by KARL PEARSON and SÖREN HANSEN, be correlated with a vital capacity below normal? KJERRULF has lately shown that in school children there is no essential difference in the chest measurements of the first- and the later-born; but he has not applied the tests described by Professor DREYER and Dr. BURRELL. It would also be of interest to compare the vital capacity with the blood pressure and the oxygen metabolism in various stages of pulmonary tuberculosis. MARIE KROGH'S recent researches into the oxygen metabolism of the body at rest in various diseases have provided numerical data of great value, and the extension of her methods of research to cases of pulmonary tuberculosis might well yield results which, in conjunction with vital capacity measurements, should add appreciably to our knowledge of pulmonary tuberculosis.

The Banner of Research.

THE growth of public recognition of the benefits derived from research, and the decreased power of the antivivisector to belittle them, are largely due to the propaganda of the Research Defence Society. Since its inception in 1908 this society has striven to educate the ignorant, appease the fanatic, and convince the reasonable man. In its quarterly reports it not only makes plain the latest attempts (sometimes well concealed) to obstruct research, but calls attention to new work and current literature. In the last report a quotation is given from an address delivered by Sir WALTER FLETCHER on March 9th to 40 Members of Parliament, and the address itself has more recently been published by the society in pamphlet form. Sir WALTER FLETCHER claimed that the application of medical science had been one of the fundamental essentials of our victory in the great war. He was right. As examples of the actual economy in pensionable morbidity effected by research he quoted the regulations against bathing in infected waters in Egypt, the surgical application of the pathology of gas gangrene, and the tests to determine the prognosis of trench nephritis. Finally, he spoke of the necessity of enabling men of the first ability to adopt research as a career by securing to them a living wage. "They do not ask for wealth, but they want reasonable freedom from care." One common fallacy mentioned in the address may be emphasised. The idea that a man can spend his novitiate in clinical practice and, having earned distinction and a competence, can then usefully turn to the investigation of the problems he has encountered, is unsound. But there is a more hopeful avenue open. Too often in the past a graduate who had qualified for a series of research scholarships found himself at 35 without an assured income or status, whereas his less brilliant contemporary had risen through conscientious routine work to a position on the scientific teaching staff of his medical school. The tendency in recent years to select for University chairs men with a good record of research, irrespective of their previous teaching experience, must be taken as an indication of brighter possibilities for the research scholar. Definite evidence that experience and skill as a teacher is as desirable an attribute in a candidate for a high teaching post as indication of capacity for research, is another question, and a personal one in each instance. The teacher whose horizon is bounded by his annual course of lectures may become pompous and dogmatic with the years; on the other hand, we all have experience of the distinguished scientist who cannot inspire or even control his class. Perchance the policy of the Medical Research Council in distributing research grants to the junior men at the medical schools will help to develop the ideal type of combined investigator and pedagogue.

Insects and Disease.

A CONGRESS is being held this week in London of our leading economical entomologists, and the programme reveals, what has long been familiar to the medical profession, that a comprehension of the life-history of insects supplies civilisation to-day with an enormous amount of information in respect to agriculture and the production of foodstuffs, while furnishing indications also of how some of our principal epidemics are spread, and how they may be avoided. It is only of recent years that there has been any close attention paid to the rôle of insects in the transmission of disease, though students of medical literature know well that in many directions the exact knowledge of to-day was the subject of forecast by the epidemiologists at the beginning of last century, who refused to acquiesce in the theory which attributed plagues and pestilences of all sorts to "miasma." But technical research had not arrived at a point when they could justify their incredulity by substituting a true ætiology, and they remained prophets of, and not participators in, the new truths. The discoveries as to the transmission by insects of protozoal parasites is one of the glories of last century's medicine, and the establishment of the fact that bacterial disease could be conveyed in a similar manner by insects has proved of equal importance. These things were recognised by the Colonial Office when the Imperial Bureau of Entomology was founded, and the activity displayed by this bureau in the identification of insects, and in the support of expeditions to the actual sites of insect-spread disease, has been of the greatest practical value to medical research. But we need not for a medical audience expatiate upon the supreme importance in modern pathology of the study of the life-history of insects.

Annotations.

"Ne quid nimis."

INTERNATIONAL HONOUR TO SIR CLIFFORD ALLBUTT.

THE Association of American Physicians is for the first time electing to its body honorary members who live outside the United States, and Sir Clifford Allbutt is the first physician from another country to be elected in this way. It is true that Sir William Osler was a member of the Association while he was holding his professorial post at Oxford, but although he was in a sense an honorary member he was also one of the founders. Following Sir Clifford Allbutt's name the names of Professors Roux, of Paris, Heger, of Brussels, and Marchiafava, of Rome, were presented. The whole of the British medical profession will endorse the honour thus paid to Sir Clifford Allbutt's eminent services in the cause of scientific medicine. It is certain that to be brought thus, and once again, into relation with Osler will have for him real if pathetic pleasure.

NUTRITIONAL NEEDS AND THE PATHOGENESIS OF DEFICIENCY DISEASE.

BEFORE the war it was generally held that Voit's standard of 3000 calories, including 118 g. of protein, constituted the optimum food intake for the 24 hours. Most nations of the world lived below this level during the years 1917–18, some of them much below, and Central and Eastern Europe cannot approach this standard at the present time. It might be thought that the experience thus obtained would have been sufficient to confirm or disprove Voit's deductions, but this is to ignore the significance of a rather warm discussion which has been going on between Rubner and Hindhede in the German medical press.

Hindhede has, of course, long stood with Chittenden for the non-necessity of a high protein intake, and along with certain enthusiastic disciples had the courage himself; to subsist for many months on a diet of bread and margarine, maintaining, it is alleged, full working efficiency. The most recent support to this thesis comes from the Hygienic Institute in Leipzig (*M.m.W.*, April 16th), where Professor Kruse and Dr. Hintze, on the results of a long series of exact experiments, inclined to the Chittenden view and put the necessary protein intake at three-quarters only of the Voit standard. It is, they say, a matter of fundamental importance for the future of the German people to live within the compass of its domestic food production; and they agree in effect with Bayliss's maxim to take care of the calories and the protein will take care of itself. But in the same number of the Munich journal Dr. Otto Kestner reviews Benedict's latest study in the Carnegie Institute, in which any reduction on the Voit standard is held to put a limit on the physical and mental capacity of the strong and healthy man. Kestner recalls that it is only within the last two generations that the world has become sufficiently rich to obtain for each individual the food-supply necessary to the full development of healthy faculties, and he regards the agitation of Hindhede, Berg, and others, as nothing less than a public danger. Something similar has occurred in Belgium, where the nominal allotment of food during the war was 2800 calories or so; but of this total Dr. J. Demoor and Dr. A. Slosse contend (*Acad. Roy. de Méd. de Belgique*, April 25th) that only 1400–1500 calories actually reached the consumer. These authors sharply controvert Starling's assumption that hyponutrition was rare in war-time Belgium, asserting rather that tuberculosis and debility played great havoc with the population, while the average Belgian male lost weight to the extent of 10 kilos. Three recent numbers of the principal Austrian medical paper have been largely occupied by a verbatim report of the address on Austria's food problem given by Professor A. Durig before the Vienna Medical Society. Of this address our Vienna correspondent gave an able summary in THE LANCET of May 15th (p. 1084). Durig concludes that Voit's standard must be maintained, in the face of almost blank despair as to how it can be done. In his concluding paragraph he points to the example of a small and isolated country without seaboard which has solved with success its own nutritional problem. What Switzerland has done and can do must be Austria's diligent aim in the coming months and years.

To keep up Voit's standard is at present a question of world-production and world-distribution, with which medicine is only indirectly concerned. But evidence is accumulating rapidly in regard to alleviatory measures, especially in Vienna, where Dr. Harriette Chick and Dr. Elsie Dalyell, representing the Committee on Accessory Food Factors, are carrying on important investigations with the whole-hearted assistance of the Austrian medical profession. A chapter dealing with this work appears in the report of the Lister Institute for 1920, just issued. Rickets, which has of late been developing in an alarming manner even in breast-fed infants in Vienna, is being staved off by allotting to nursing mothers a daily ration of butter, 50 g., and raw swede juice, 30 g. Osteomalacia, which became common last year in both sexes and at all ages and decimated especially the convents, has been shown to be probably due to deficiency of the fat-soluble accessory substance. Scurvy is yielding to extra antiscorbutics in the form of swede juice, orange juice, and neutralised lemon juice. These are only palliatives, but palliatives which are saving many lives and helping to tide over by medical means an emergency which can only be dealt with in its entirety by enlightened statesmanship.

In this connexion it is interesting to refer to the valuable series of researches into the pathogenesis of deficiency disease, continued by Lieutenant-Colonel R. McCarrison, at the Pasteur Institute of Southern India, Coonoor, further contributions on the same subject being reported in the *Indian Journal of Medical Research* (Vol. VII., No. 2). In THE LANCET of July 12th, 1919, and Feb. 14th, 1920, we commented generally on Colonel McCarrison's previous researches.

The reports now published, five in number, deal respectively with the histopathology of deficiency diseases, the influence of a scorbutic diet on the bladder, the effects of autoclaved rice dietaries on the gastro-intestinal tract of monkeys, the general effects of deficient dietaries on monkeys, and the occurrence of recently developed cancer of the stomach in a monkey fed on food deficient in vitamines. With regard to the results of his experiments on the general effects of deficient dietaries on monkeys, Colonel McCarrison reaches the following conclusions—namely, that dietaries which are deficient in vitamines, and in protein, and at the same time excessively rich in starch, or in fat, or in both, are potent sources of disease, and especially of gastro-intestinal disease. An excess of fat, in association with deficiency of water-soluble B vitamine and protein, and superabundance of starch, is peculiarly harmful to the organism. He found also that certain dietetic deficiencies greatly favoured the invasion of the blood and tissues by bacteria: especially was this the case when deficiency of vitamines and protein was associated with an excessive intake of starch. As life cannot be maintained in monkeys (*Macacus sinicus*) for much longer than a hundred days on a dietary almost wholly devoid of water-soluble B vitamine, it would appear that complete absence of this vitamine from the food of human beings is of less practical importance from the point of view of disease production than is its subminimal supply. Complete deprivation of water-soluble B vitamine, especially in the presence of imperfect balance in other essential requisites of the food, will lead to rapid dissolution and death; subminimal supply of this vitamine will lead, in like circumstances, to slow dissolution and disease.

Finally, Colonel McCarrison makes the important suggestion, and one which must be of special interest to medical men in general practice—namely, that the findings recorded by him may afford some explanation of the genesis of that great mass of ill-defined gastro-intestinal disorders and vague ill-health which forms so high a proportion of human ailments at the present day.

MINERS' NYSTAGMUS.

IN the *British Journal of Ophthalmology* for April there is a full report of the important discussion organised by the Illuminating Engineering Society upon the illumination of mines, with particular reference to miners' nystagmus. The chairman justly remarked that Dr. T. Lister Llewellyn, who opened the discussion, had produced an enormous amount of evidence in favour of the view that the essential cause of miners' nystagmus is deficient illumination. On the present occasion the chief interest of Dr. Llewellyn's paper depended on the practical measures which he recommended to improve illumination. Incredible as it may seem, the source of light which gives the highest candle-power at the coal-face is the tallow candle. By carefully spreading out the wick two candle-powers may be obtained. In mines where there is a danger of fire-damp open lights cannot be used. The modern oil safety-lamp rarely gives more than one-half candle-power, and the modern electric lamp in use gives about one candle-power. The introduction of electric lamps has already effected a certain improvement in the conditions in many mines, but its light is still insufficient, and any possible improvement is necessarily limited by the weight of the battery. By bringing the light as near as possible to the surface of the coal-face which is being worked upon something can be done. A form of cap-lamp was demonstrated at the meeting which, according to Dr. Llewellyn, met the requirements satisfactorily. The battery is carried in the miner's belt and connected with the lamp by a flexible wire, the weight being 2¾ lb. Mr. Bishop Harman suggested that inventors should turn their attention to the production of a vapour-lamp capable of giving an efficient and harmless light. Other speakers dwelt on other aspects of the problem—the quality and colour of the light, the possible toxic effect of gaseous emanations from the coal-face, and the undoubted fact that nystagmus is a disease of the nerve centres, rather than of the eyes, and that it has some relation to neurasthenia. A notable feature of the discussion was that no one was found to defend the view that the cramped position of the miner at his work is mainly responsible for nystagmus; this is in contradiction to the teaching of Mr. F. L. Hoffman's pamphlet, issued by the American Bureau of Mines, but the American report has no basis of personal experience. Whatever factors other than deficiency of illumination may enter into the causation of nystagmus, it is amply proved that the most important is the amount of light reflected from the surface of the coal at which the miner is working, and therefore the time is ripe for preventive action. There is, it appears, a Government inquiry now sitting on the subject, and there is also being arranged a joint inquiry of ophthalmic surgeons and lighting engineers. There ought soon to be some practical result of so much deliberation.

ADVERTISEMENTS IN THE MEDICAL PRESS.

IN a recent number of THE LANCET[1] a report appeared of a meeting of the Worcestershire County Council at which considerable discussion took place with regard to certain salaries offered by the Council in connexion with their medical service scheme, and with regard to the attitude of the *British Medical Journal* and *The Lancet* towards advertisements of the posts in question forwarded to them by the Council. Both papers had refused to accept advertisements which offered a less salary than £500 per annum for such posts, and the Council, although warned by a medical member that on a former occasion of a similar character advertisements in the daily press had produced no replies, decided eventually to repeat the experiment. In particular, Mr. Willis Bund, the chairman, and Colonel Wheeler, the vice-chairman, protested, the former against allowing the medical press "to dictate" to the Council as to what salaries should be given, and the latter against the Council "sitting down" under the treatment thus accorded to it. Neither of these two gentlemen seems to have appreciated the position of these two papers, which exist not merely to supply the medical profession with information upon matters of interest to it, including opportunities for competing for public appointments, but also in order to advance and maintain the interests of the profession by every honourable means. The possibility of a learned profession considering that a salary below a certain figure should not be offered to or accepted by its members should at least have been understood by Mr. Willis Bund, and that the organs of that profession should give expression to its views should not have appeared to him unnatural. He is a barrister, a member of a profession in which the strictest rules exist governing many questions of remuneration. We need only refer to the prescribed proportion to be borne by the junior's fee to that of his leader when counsel appear in court, or to the special conditions under which a barrister is briefed on a circuit of which he is not a member, in order to remind any lawyer of the existence of these rules. They refer, it is true, to strictly professional work for which barristers are "briefed," and we are not aware of any interference with the acceptance of appointments. In other words, individuals can be sweated if they choose, and their profession makes no effort on their behalf. At the same time, we conceive that if the Government were to decide, for example, that the remuneration of county court judges or masters of the High Court was to be reduced for future appointments by 50 per cent. the bodies representing the two professions would have something to say by way of protest. So, no doubt, would the legal press, although its relations to the profession for which it caters hardly coincide with our own, and might not impose on it the duty of refusing to advertise underpaid posts for barristers and solicitors. There are, however, intrinsic differences between the two professions which affect the position which they occupy with regard to their members. We do not desire to advise lawyers as to what it is consistent with their dignity to accept by way of remuneration as members of a learned profession or as to what is necessary for their maintenance. Outside any such questions as these, there is, with regard to medical appointments, a more important point to be considered. The medical profession is responsible for the public health, and it realises that it is not in the public interest that posts should be held by men whose experience and training have not qualified them to do so with credit to themselves and with advantage to the public.

---

[1] THE LANCET, May 1st, 1920, p. 979.

In the particular case under consideration the chairman actually admitted that he had had a letter from the Ministry of Health stating that tuberculosis officers should have special qualifications and experience, and expressing a doubt as to whether the salary offered would be sufficient to secure them. Mr. Willis Bund "objected to this sort of pressure being put upon local authorities." We can only express our satisfaction at the attitude taken up in the public interest by the public authority. For ourselves, if refusal to insert the advertisements of the Worcestershire County Council should appear to that body to be arbitrary or dictatorial, we would assure its members that it is neither. It is due to our full appreciation of the requirements of the Council and of those of the public with the care of whose health it has been entrusted.

IODINE DISINFECTION.

THE efficiency of disinfection of the skin with iodine has recently been the subject of painstaking investigations by Dr. Johan Seedorf,[1] a countryman of Professor Rovsing, whose criticism of this popular method of disinfection has done much to prevent its acquiring the unimpeachable security of stereotyped orthodoxy. Rovsing's indictment, it may be remembered, was supported by cases in which tetanus or gas phlegmon developed in spite of preoperative treatment of the skin with iodine. Dr. Seedorf's investigations were made both in vivo and in vitro. With regard to the latter, he found that iodine (0·1 per cent.) in an aqueous solution of potassium iodide kills staphylococci in one minute, but tetanus spores only after two hours. This disinfectant action of iodine increases with the strength of the solution only up to a certain point; its maximum efficiency is exhibited by a 1 per cent. solution. In confirmation of earlier investigations, it was found that, though alcohols readily kill the ordinary bacteria, their action on the spore-forming group is very slight, whereas that of iodine is much more effective. The effect of iodine on the skin was studied on rats' tails as well as on human skin. It was noted that the disinfectant action of iodine on a rat's tail was not checked by previous washing with soap and water, and this was so whether the skin was still moist or not after the washing. The same observation was made on the human skin, and this point is the more interesting as some advocates of iodine disinfection have insisted on dryness of the skin being an essential preliminary to the application of iodine. Dr. Seedorf made a series of interesting comparative investigations into the effect of iodine sterilisation as practised in three different surgical departments. All used a 5 per cent. solution of tincture of iodine, but the ritual differed in the various departments according to the inclination of each surgeon and the urgency of the operations. At the beginning of each operation a piece of skin, which had been treated with iodine, was excised and submitted to a bacteriological examination. Although the skin was found to be sterile only in 42 per cent., healing by first intention was effected in 90 per cent. of the cases in which drainage was not maintained. In 3 per cent. abscesses formed in the operation wound, and stitch abscesses formed in 7 per cent. In all these post-operative septic cases the excised portions of skin yielded micro-organisms. But in spite of these shortcomings Dr. Seedorf recommends iodine disinfection, especially when it is preceded by mechanical cleansing, and when three paintings of iodine are given at intervals of five to ten minutes during the last half hour before operation. He employs a 1 per cent. solution of iodine dissolved in 96 per cent. of ethyl-alcohol. If time permits there should be an interval of about 12 hours between the soap-and-water cleansing and the application of the iodine. In emergencies soap-and-water washing should be omitted in order that repeated applications of iodine may be made.

THE CARE OF EPILEPTICS IN AMERICA.

THE twenty-sixth annual report of the New York State (Craig) Colony for Epileptics contains, as in former years, a good deal of pertinent material by the medical superintendent, Dr. W. T. Shanahan, about the care of epileptics. Dr. Shanahan lays stress on the importance of individualisation in treatment, pointing out that the whole of the environment, including diet, drugs, and especially occupation and education, must be considered along individual, rather than along general, lines. Not the least important factor in this environmental adjustment is the appointment and retention upon the staff of the best type of men and women; and Dr. Shanahan pleads for money to provide suitable diversion and recreation for the employees who have to live, day in and day out, among the patients. Such expenditure, he rightly argues, would be an indirect but effective means of treating the patients themselves. Little appears in this report about the use of bromides. Those who have followed the work at the Craig Colony will remember that between 1904 and 1915 the average daily dose of bromide was reduced from 20·5 to 0·6 gr. per patient, and that during the same period the incidence of fits was, if anything, rather diminished. Dr. Shanahan continues to report favourably upon this very restricted use of bromide, and remarks that cases of status epilepticus and serial seizures have been much less frequent than in former years, when bromides were used more freely. The omission in the report of any reference to psychogenic factors in epilepsy or to psycho-therapeutics in its treatment is surprising, as Dr. Pierce Clark, visiting neurologist to the colony, has long been recognised as a pioneer worker in this aspect of the ætiology and treatment of the disease. Epilepsy is essentially a disease arising in childhood; and it is during childhood that general environmental adjustment is of paramount importance; for it is then that we have the best chance of arresting fits, and of combating retarded or abnormal mental development. It is a pleasure, therefore, to note that a supervisor of education is to be appointed, for the first time, at the Craig Colony. One only regrets that the colony school is so small and financially limited.

---

[1] Acta Chirurgica Scandinavica, 1920, vol. lii., Fasc. v.

A few statistics will best indicate the present scope of the work. The number of patients at the colony is 1350, and they are under the charge of ten resident and eight visiting medical officers—an allowance which strikes us in this country as very generous. Of 5000 patients admitted since the opening of the colony, only 10 per cent. are reported as being mentally normal or approaching that level, while 10 per cent. showed signs of paralysis originating at birth or in infancy. Some 3700 patients have left the colony, of whom more than half were removed by death, 4 per cent. to insane asylums, and only 2·4 per cent. were reported as recovered, the standard of recovery being freedom from seizures for two years or longer. The net cost per head has risen slightly, from $268 in 1914 to $290 in 1919. One of the most valuable features in the Craig Colony reports is to be found in the post-mortem records. There are 103 of these in the present volume, making a total series of 1039 autopsies on epilepsy. The classification of the findings might not be generally acceptable. For instance, of the 103 brains examined this year, we are astonished to learn that no less than 89 per cent. were found to show "definite gross lesions." This surprising figure is arrived at by including among definite gross lesions such conditions as congestion, anæmia, or œdema of the brain, icteric colouring of the brain, asymmetry of the calvarium, and even bruises of the scalp.

TRANSIENT PERICARDIAL FRICTION IN CORONARY THROMBOSIS.

IN the *Albany Medical Annals* for April Professor L. W. Gorham has called attention to a sign of coronary thrombosis which has been almost unrecognised — transient pericardial friction. He reports six cases, in three of which the diagnosis was verified by necropsy. The following is an example:—

A lawyer, aged 57, whose health had been excellent, was seized with severe pain on Dec. 24th, 1917, while walking up a rather steep hill several hours after luncheon. When he sat down the pain ceased. Next day after the evening meal the pain recurred when walking and ceased on resting. In the evening it returned, with much belching of gas. About an hour after going to bed he was seized with agonising pain under the sternum. When seen at 3 A.M. his chief difficulty was severe substernal pain and an effort to vomit or belch gas. The pain did not radiate to the arm. His colour was grey, with slight cyanosis. The pulse was 100, full, bounding, and of high tension. Morphine hypodermically and nitroglycerine failed to relieve the pain. After four hours he felt easier. A complete examination was not made until next morning. There were ashy cyanosis, slight œdema of the bases of the lungs, increase of cardiac dullness to the right, rather distant regular heart sounds, and a delicate to-and-fro friction rub. The blood pressure was 120 systolic, 70 diastolic. For five days there was fever up to 101° F., with a pulse of 110 to 120. The friction came and went. Under rest and digitalis he gradually improved and the pulse and temperature became normal on the ninth day and the rub disappeared after two weeks. Suddenly, without warning, he died in bed on the thirty-seventh day after the onset. The necropsy showed the right heart and left ventricle considerably dilated. The anterior wall of the left ventricle in the area supplied by the anterior branch of the left coronary artery was thinned and softened and in the middle was a yellowish area of necrosis. Over the area of softening there was slight roughening of the epicardium and irregular areas of ecchymosis. The right coronary was narrowed by calcification. The left coronary was also calcareous and occluded by a friable reddish thrombus, but the distal parts of the coronary arteries appeared normal. The aortic valves were thickened. The papillary muscles had a yellow to greyish mottled appearance.

The six cases showed the following points of similarity.

1. Sudden attack of agonising pain, usually substernal, frequently radiating to the left arm and of longer duration than in an ordinary attack of angina, often lasting for several hours. Following this pain or soreness might persist for days. In some cases the pain was referred to the epigastrium, suggesting an abdominal catastrophe. The patient looked shocked, with ashy-grey moist skin and rapidly compressible pulse. (Such cases have been operated on). 2. Fever coming on usually in 24 hours and lasting four or five days. 3. A pericardial rub coming on within the first few days, transitory, often recurrent. 4. Signs of cardiac decompensation—tachycardia, arrhythmia, feeble heart sounds, falling blood-pressure, increase of cardiac dullness to the right, disappearance of a systolic murmur present before, signs of œdema of the lungs, albuminuria, and, in late stages, general œdema. Morphine and nitroglycerine failed to relieve the pain. There may or may not have been attacks of angina pectoris preceding the seizure. Coronary thrombosis may occur where recent examination has failed to show evidence of cardiac or vascular disease. There may or may not be an exciting cause, such as over-exertion, over-eating, or excitement. All the cases except one were fatal, but one patient lived for three months after the first attack. One patient recovered and could work actively five years after the attack.

On turning to the literature allusions may be found to this clinical picture, but the text-books do not mention pericardial friction in coronary thrombosis. In 1884 Leyden described such a case but failed to interpret it correctly. In 1892 Kernig mentioned pericarditis following an attack of angina. In 1910 Sternberg described the syndrome in the *Wiener Medicinische Wochenschrift* under the designation "Pericarditis Epistenocardica." Professor Gorham's observations of six cases within a few years, taken with the fact that fibrinous pericarditis is not an uncommon post-mortem finding in coronary thrombosis, suggest that the condition is more common than might be supposed and that it has frequently been overlooked.

SYPHILIS OF THE PROSTATE.

Dr. Loyd Thompson,[1] of Hot Springs, Arkansas, whose article on Syphilis of the Bladder recently received notice in THE LANCET,[2] has written an equally interesting paper on Syphilis of the Prostate, in which he reviews the literature and reports a personal case. Only 24 cases purporting to be syphilis of the prostate have been recorded, and of these only 12 can be accepted as authentic. It can therefore be concluded that the condition is either very rare or that it is seldom recognised. In 7 of the 12 authentic cases in which the time after infection is stated it varied from three months to 15 years. The age of the patients ranged from 18 to 62, the average being 40. The most frequent clinical symptom of syphilis of the prostate is pain which may be slight or violent, and in some cases is independent of micturition, but in most cases is aggravated by the act Pollakiuria is the next most frequent symptom, but in none of the cases was it very marked A slight urethral discharge was noted in three cases, and in several a discharge was produced by prostatic massage Less frequent symptoms are hæmaturia, a feeling of a foreign body in the rectum, painful defæcation, painful coitus, and more or less residual urine As a rule the urine is somewhat cloudy, and contains pus, muco pus, epithelial cells, and sometimes red blood corpuscles There is nothing pathognomonic either in the symptoms or rectal findings, so that the diagnosis must be made by exclusion, the history, the presence or absence of other symptoms of syphilis, including the Wassermann reaction, and the results of specific treatment *The prognosis is good, as in all the* authentic cases improvement, and in most complete recovery, occurred under specific treatment

FEDERATION OF MEDICAL AND ALLIED SOCIETIES

A MEETING of the Executive Council of the Federation was held on Thursday, May 27th, at 11, Chandos street, Cavendish square, when the report of the General Purposes Committee in regard to a submission from the Medico Psychological Association of Great Britain and Ireland was considered, and it was resolved that a letter be sent to the Lord Chancellor, the Minister of Health, and the medical Members of the House of Commons urging the need of immediate legislation for the efficient treatment of mental disorders in their early stages It was also reported that, in view of the request of certain nursing and allied organisations, a conference had been held, when the bodies chiefly concerned had agreed to the following resolution —

> That there should be on the Consultative Council of Medical and Allied Services of the Ministry of Health a qualified nurse who should also be a qualified midwife and who at the same time should represent the masseuses and sanitary inspectors '

The Executive Council resolved to support this resolution by forwarding a letter on the matter to the Minister of Health and the medical Members of Parliament

A discussion of the Interim Report of the Consultative Council of Medical and Allied Services of the Health Ministry followed, the value of which was enhanced by the good attendance present and by the fact that Lord Dawson, who is a member of the Council, answered very fully many questions which arose during the discussion It was considered that a public and independent inquiry into the working of the National Insurance Medical Benefit and a census of the hospital beds in the country were necessary preliminaries to many of the reforms advocated The following organisations which had applied for corporate membership of the federation, were elected —London and Counties Medical Protection Society, National Union of Trained Nurses, School Dentists' Society, Women Sanitary Inspectors and Health Visitors Association The names of 42 medical men and women were submitted as applicants for associate membership and were declared duly elected The Medical Committee of the House of Commons has nominated Captain W E Elliot, M P, its secretary, as a watching representative on the Executive Council of the Federation, and Captain Elliot was elected a member of the Council

THE TREATMENT OF LEPROSY

AN account was given in THE LANCET of May 1st of the general recommendations of the Calcutta Leprosy Conference since which the papers on the treatment of the disease read before the conference have been published in India (*Indian Medical Gazette*, April), which furnish important confirmation regarding the value of Sir Leonard Rogers's method of injecting soluble preparations of the unsaturated fatty acids of chaulmoogra and other oils, together with some further progress of his researches

During the past year reports have been received of the trial, organised by the Mission to Lepers, of both sodium gynocardate intravenously and sodium morrhuate subcutaneously and intravenously from 18 leper asylums, an analysis of which was read by Dr E Muir, who had previously recorded favourable results from this line of treatment Although many of the cases were advanced ones and the treatment was not long enough (in some cases not exceeding two months) to afford the best results, yet in 300 cases improvement was noted in 72 per cent and much improvement in 32 per cent, including several cases in which the lesions entirely disappeared The results were practically the same with both drugs, although most of the observers thought the gynocardate was more effective in anæsthetic cases, but more troublesome to carry out on account of its irritant effect on the veins Dr Muir concludes "The result of this widely carried out experiment can leave but little doubt that a distinct advance has been made in the treatment of leprosy An interesting report by Dr Ernest Neve of his trial of the drugs in Cashmir is also recorded, as well as a suggestive paper by Dr Muir on the after treatment of the disease A paper by Dr M Cathew, of Siam reporting the further progress of his trial of sodium gynocardate A was also read, and is of interest owing to the longer duration of his trial, which he summarised as follows In 4 the lesions have completely disappeared for from 6 to 18 months, in 8 there is very marked improvement, although in 2 of them there has been some retrogression, in 1 general improvement, in 1 slight improvement, and in none no improvement Four other cases were lost sight of, 2 of whom had very greatly improved

Sir Leonard Rogers also summarises his results up to date in 71 cases as showing 1 not improved 12 slightly improved, 32 greatly improved, and 26 lesions disappeared, and mentions 4 of his earlier cases who have now remained free from all visible signs of the disease for over two and a half years Six of his later series have remained free for over a year but he records 5 relapses due to early cessation of the treatment, and states that it is too early to speak of permanent cures in this series He goes on to point out that the success of sodium morrhuate in leprosy establishes the important principle that other unsaturated fatty acids than the peculiar series found in chaulmoogra oil are of value in the treatment of leprosy, which has led him to make further preparations from oils with a high iodine value indicating a large proportion of these substances One of these made on this theory from soya bean oil has proved to be practically unirritating on injection into patients, while a short trial indicates that it is considerably more active in leprosy than previous preparations thus holding out hope of still further advances in the near future, when an experienced whole time investigator will take up the research in the Calcutta School of Tropical Medicine

A paper in the same issue of the *Indian Medical Gazette* is worth attention It is on the use of sodium morrhuate in advanced pulmonary tuberculosis The subjects, who had tubercle bacilli in the sputum, were 28 sepoys at Quetta, at the date of the records 8 (in addition to 4 early cases) had been discharged cured by a medical board and 6 more were fit for discharge (and were passed by the board a little later), 4 were improving, 4 were worse, 3 were in a stationary condition, and 1 died before more than two or three injections could be given. Even allowing for the favourable dry climate of Quetta these results, obtained in five months, are very encouraging.

THE TRAGEDY OF LOUTH.

THE Ministry of Health has been prompt to initiate measures for the prevention of any epidemic evils that might follow on the complete destruction of a large area of the town of Louth. The structural repair of the damaged drainage system is to be immediately taken in hand, and strict injunctions have been issued that all drinking-water should be boiled. The work of salvage is proceeding under the eyes of medical officers sent down from the Ministry, and every precaution is being taken that the tragedy of the flood should not be followed by the tragedy of disease.

THE LEAGUE OF RED CROSS SOCIETIES: THE MEDICAL ADVISORY BOARD.

A PROGRAMME of the General Medical Department of the League of Red Cross Societies has been drawn up by Dr. Richard P. Strong, general medical director, in anticipation of the first annual conference of the Medical Advisory Board of the League, which will meet in Geneva on July 5th. Eight nations will be represented at this conference by distinguished members of the medical profession, whose duty it will be to consider this medical programme, to make recommendations upon it, and to advise concerning the medical work to be undertaken by, or in the name of, the League. Belgium, Brazil, Denmark, and Japan each contribute one of the Board's 15 members; Italy has 2 representatives; and France, Great Britain, and the United States each send 3 delegates.

Dr. J. Bordet, director of the Pasteur Institute at Brussels, is the Belgian member of the Board. Brazil is sending Dr. Carlos Chagas, director of the Oswald Cruz Institute at Rio de Janeiro. From Denmark will come Professor T. H. Madsen, of the State Serum Institute at Copenhagen, while the Japanese representative is Professor Kinnosuke Miura, of the Imperial University of Tokio. Professor Dr. Giuseppe Bastianelli, physician and pathologist to the Polyclinic Hospital at Rome, and Professor Aldo Castellani, professor of tropical diseases at the London School of Tropical Medicine, constitute the Italian delegation. The French members of the Board are Professor Emile Roux, director of the Pasteur Institute at Paris and chairman of the Cannes Conference, at which the League of Red Cross Societies was organised; Professor Albert Calmette, subdirector of the Paris Pasteur Institute; and Dr. Léon Bernard, professor of hygiene at the University of Paris. Great Britain is represented by Colonel S. Lyle Cummins, professor of pathology at the R.A.M.C. College, London, and during the war adviser in pathology to the British armies in France; Sir Walter Fletcher, secretary of the Medical Research Committee; and Sir George Newman, chief medical officer of the Ministry of Health. Dr. William H. Welch, director of the School of Hygiene and Public Health of the Johns Hopkins University; Dr. Hermann M. Biggs, New York State Commissioner of Health; and Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, will be the American members of the Board.

The Medical Advisory Board of the League of Red Cross Societies will at its first meeting elect its officers and adopt rules to govern its proceedings. The decisions of the Board, when approved by the chief officers of the League, will outline the medical policy to be pursued. While the regular meetings of the Medical Advisory Board will be held annually, emergency meetings may be called by the League's director-general or Board of Governors. In the intervals between meetings the members of the Advisory Board are kept informed by correspondence of the health work being undertaken or contemplated by the League. They, in turn, keep the general medical department of the League informed of the progress of health work in their respective countries, and call the attention of the League to any fields which they believe it may profitably enter.

IN Dr. George E. Morrison, Political Adviser to the Government of China, the medical profession has lost one of its most distinguished representatives, although his work of world-wide importance lay in other fields. The story of his adventures and wanderings, no less than of his statesmanlike activities, has been told during the week in the press of the country; his death while still in middle age and full of plans for the future is a deplorable event.

A DINNER will be held on Tuesday next, June 8th, at the Connaught Rooms, Great Queen-street, to celebrate the services of the Royal Army Medical Corps, and the civilians attached to it, during the great war. Sir Alfred Keogh will be the chief guest, and the Secretary of State for War, Mr. Winston Churchill, Field-Marshal Lord French, Field-Marshal Lord Haig, and many distinguished generals will be present. Lord Derby, Lord Midleton, Lord Edmund Talbot, General Seely, Mr. H. J. Tennant, and Colonel Sir Edward Ward are acting as a committee, and all communications should be addressed to the last named at 10, Grosvenor-street, S.W.

THE retirement of Sir John Bland-Sutton from the active staff of the Middlesex Hospital, where he was until to-day senior surgeon, is a thing to make us regret the remorseless passage of time. As a student and later as a member of the staff, Sir John Bland-Sutton has been associated with the Middlesex Hospital for 42 years, and the inception and endowment of the Bland-Sutton Institute of Pathology, a remarkable piece of individual generosity, is only one of the many advantages to the hospital which can be traced to his efforts. His release from active hospital work will enable Sir John Bland-Sutton to give still more time, as President of the Association of British Surgeons, to the scientific side of medicine, the development of which he has so much at heart.

A MEMORANDUM on clinical units in medical schools has been issued during the week by the University Grants Committee, 12, Old Queen-street, Westminster, stating the case for the units, and detailing the acts of legislation and the official or other reports which have led to their establishment. The memorandum sets out the advantages and also the drawbacks which may attend the latest development in medical education, and enumerates the essentials of the clinical system. These may be summarised as the provision of satisfactory training for the students in suitable and properly correlated hospitals and schools under appropriate and competent persons. It is postulated that the professor or director should devote the greater part of his time to teaching, treatment, and research, should have control of hospital beds and an out-patient department, ample laboratory accommodation and scientific equipment, and an adequate whole-time and part-time staff.

THE GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION.

THE opening of the summer session of the General Medical Council took place on June 1st, under the presidency of Sir DONALD MACALISTER. It was announced that Mr. H. J. Waring would be absent for the session in the United States, and that Dr. David Hepburn found the pressure of examinational work too great to allow of his attendance.

President's Address.

In his opening address he recorded the retirement of Dr. David N. Knox, Sir Bertram Windle, and Sir Charles Tomes, treasurer to the Council since 1904, and paid a tribute to their past services. He then welcomed as new members: Dr. James A. Adams, representative of the Royal Faculty of Physicians and Surgeons of Glasgow; Dr. R. A. Bolam and Mr. E. B. Turner, Direct Representatives of the practitioners of England and Wales; and Mr. Norman G. Bennett, appointed by the Crown, in place of Sir Charles Tomes. Sir Donald MacAlister congratulated the following members of the Council on whom honours had been conferred—K.B.E., Sir James Hodsdon; C.B.E., Colonel Waring, Dr. Caton, and Dr. Langley Browne; O.B.E., Mr. Cockington. He continued:—

"Under the Ministries of Health Acts, Consultative Councils, for the purpose of advising the respective Ministers in regard to medical and allied public services, have been constituted in the three kingdoms, and are already at work. To all of them members of this Council have been appointed, and it will thereby be kept in touch with their activities. A number of draft and other Orders in Council under the Acts have been transmitted for its consideration to the Executive Committee, but so far none of these have dealt with questions other than administrative and formal. On May 17th an Order was issued giving effect to a desire of the Executive Committee, by which the duties of the Secretary of State in regard to the Anatomy Acts are in England and Wales transferred to the Minister of Health. It is to be hoped that the new arrangement will lead to much needed improvements in the provision made for the practical teaching of anatomy and surgery.

Acting on your instructions, I was enabled by the courtesy of the Lord President to call the attention of the English Minister of Health to an apparent omission from the Nurses Registration Bill introduced by him. No provision was made, as in the Midwives Acts, for communicating the rules framed by the General Nursing Council to the Executive Committee before approval by the Minister. Dr. Addison considered the point, but decided that such a provision was in this case unnecessary, as the rules in question, unlike those of the Central Midwives Board, do not purport to 'regulate the practice' of nurses, but deal mainly with details of administration. Moreover, such rules have, unlike those for midwives, to be laid before Parliament prior to approval. The Minister accordingly did not favour any amendment of the Bill in the sense suggested, and the Lord President concurred in his view. The point will, however, have to be kept in mind, should it hereafter be proposed to make rules, under statutory authority, for regulating the practice of nurses in surgical and medical cases as that of midwives is regulated in obstetrical cases. Sir Jenner Verrall has been appointed a member of the General Nursing Council for England, and will, no doubt, keep us informed on the subject."

The President then referred to the reintroduction by Sir Henry Craik of Lord Morley's Bill of 1912 for the extension of the time allowed to prepare for the election of Direct Representatives to the Council, and for providing that in general such elections shall be held simultaneously. If the measure passed into law, he said, considerable economies on the part of the branch councils and of candidates would be effected, and the convenience of the electors would be better served.

The legislation for the amendment of the Dentists Act, he said, had not yet been initiated in Parliament, though it was stated officially that draft Bills were soon to be introduced. It appeared that one Bill would be required to deal with dental registration, and that other measures would be necessary to give effect to such proposals for the improvement of dental service as were set forth in the Report of the Departmental Committee on Dental Practice—these had already been considered by the Council. It would be necessary to instruct either the Executive Committee, or a special committee appointed for the purpose, to watch the progress of legislation during the summer, and to take such steps as might be required to ensure that effect was given to the conclusions of the Council. Sir Donald MacAlister commented with approval on the Dangerous Drugs Bill, which imposed restrictions on the import, export, manufacture, and sale of opium, cocaine, &c., with the object of preventing dangerous abuse of these drugs. He pointed out that it gave power to the Government to make regulations for the issue by medical practitioners of prescriptions containing any such drug, and for the dispensing of such prescriptions. During the war similar regulations were in operation, and the question of their continuance had now assumed an international aspect. The profession, which best knew the nature and extent of the evil, would probably be the first to welcome wisely-devised measures for checking it, even if these embodied some fresh restrictions upon professional freedom. He continued as follows:—

The Registers.

"The new Medical Register confirms the forecast on which I ventured in November.[1] On the Home List only 872 practitioners were registered in 1919, but no fewer than 450 were registered in the Colonial and Foreign Lists. The result is that the total number (1322) of new names is higher than in any year since 1915. The proportion of women practitioners increases, and is likely to increase rapidly during the next year or two. I learn, however, on good authority that their services are in less demand than during the war, and that newly-qualified women are finding difficulty in obtaining suitable opportunities for professional work. Supply and demand will, no doubt, adjust themselves in time, but in view of the large entry of women students it is proper to warn those concerned that, in the meantime, individual disappointments may be encountered. The women students who are now well advanced in their curriculum may not all at once find openings for practice after attaining to qualification. The profession of medicine is, in regard to women, affected like other occupations, by the return to civil life of large numbers of ex-Service men as students and practitioners. To these men the country owes special consideration, and they ought to receive it. But inevitably they tend to displace a proportion of the women who so capably carried on the work of the profession during their absence abroad.

The Medical Students Register indicates that the depletion of our professional ranks by the wastage of the war will in a few years be much more than made good by the addition of newly-qualified men. No fewer than 3420 medical students (men and women) were registered in 1919, as compared with 1600 in 1914. The number of registrations, indeed, exceed by over 1000 the highest previously recorded—namely, in 1891—when for special reasons the number rose to 2405. The sudden increase cannot at once be met by a corresponding expansion of our educational resources, and the strain thrown upon the medical schools of the country is therefore for the time excessive. There is reason to think that most of the schools would welcome an ebb in the tide of applicants for admission, until it is seen that the profession can absorb the large numbers aspiring to enter it, and until more adequate provision is made for their effective instruction and training. In the departments of anatomy and operative surgery, of midwifery, and of clinical medicine, the existing provision is no longer fully adequate to the new demands.

The Dentists Register is stationary. The figures for the last three years are respectively 130 (1917), 131 (1918), 128 (1919). But there is an assured prospect of an advance by the year 1922, for the number of dental students entered on the Register in 1919 has risen to 612, as compared with 294 in 1914. In order more clearly to mark the sources of supply, an improvement has been made in the Medical and Dentists Registers, whereby the numbers of practitioners added respectively to the Home, Colonial and Foreign Lists are set forth in separate tables.

The cost of paper and of printing has so risen that impressions of the Registers can no longer be produced at the present authorised price. It may therefore be necessary to approach the Commissioners of the Treasury with a request that the price may be fixed at a sum sufficient at least to cover the actual cost of production.

The cycle of inspections of qualifying examinations, ordered by the Council, has been begun. Some of the reports have been already received, and will be considered by the proper committees during this session. For the Public Health Examinations we have been fortunate to secure the services as our inspector, of Dr. Robert Bruce Low, C.B., lately assistant medical officer of the English Local Government Board. For the Final Examinations for medical degrees and diplomas our inspectors are Dr. Howard H. Tooth, C.B., C.M.G., in medicine; Sir Hector C. Cameron, C.B.E., in surgery; and Sir William J. Smyly in midwifery. Members of the Council have also been good enough to act as visitors at one or more examinations, and as provided in the Standing Orders they will present their separate reports to the committees concerned."

Education and Examination Committees.

Sir Donald MacAlister said that the Education Committee was considering the question of instruction in medical ethics and the relations of practitioners to the State, the teaching of practical midwifery, and the place assigned to the preventive aspects of medicine in the curriculum of professional study. The time was ripe, he urged, for some "reconstruction" in respect of the extent and content of the several stages and departments of the medical course. The Council was accumulating from various sources ample materials both for a survey of existing conditions and for a reconsideration of its own standing resolutions on professional education and examination. The Examination Committee would submit analyses of the annual tables furnished by the licensing bodies, and would also report on the practice of the licensing bodies in respect of teaching and examination in ophthalmology, with reference to the Council's resolution of last year. The Council's finances were in a satisfactory condition, since the treasurers had been able to report for 1919 a surplus of income over expenditure of £874.

Sir NORMAN MOORE proposed a cordial vote of thanks to the President for his address, with the request that he allow it to be printed and incorporated in the minutes of proceedings. In doing so, he alluded to the conferment on the President of his recent honour, Chevalier of the Order of the Crown of Italy, and expressed his own and his colleagues' warm congratulations.

---

[1] THE LANCET, 1919, ii., 991.

Dr. NORMAN WALKER seconded and the vote was carried by acclamation.

Committees.

The following were appointed to constitute the Executive Committee: Sir Gilbert Barling, Sir Norman Moore, Mr. Waring, Dr. Macdonald, Dr. Norman Walker, Sir James Hodsdon, Sir Arthur Chance, Sir John Moore.

The selection for the Penal Cases Committee was: Sir Francis Champneys, Dr. Macdonald, Sir Norman Walker, and Sir Arthur Chance.

The constitution of the remaining committees was as follows:—

Business Committee.—Dr. Norman Walker (Chairman), the President, Sir Francis Champneys, Dr. Macdonald, Dr. Magennis.

Pharmacopœia Committee.—The President (Chairman), Sir Norman Moore, Dr. Hopkins, Dr. Russell Wells, Dr. Caton, Dr. Norman Walker, Sir John Moore, Dr. Kidd, Dr. Matthew Hay.

Finance Committee.—Sir Norman Moore (Chairman), the President, Sir James Hodsdon, the Junior Treasurer, Sir Arthur Chance.

Dental Committee.—The President (Chairman), Mr. Waring, Sir James Hodsdon, Sir Arthur Chance, Mr. Bennett (in place of Sir Charles Tomes).

Dental Education and Examination Committee.—Sir James Hodsdon (acting Chairman), the President, Mr. Waring, Sir Arthur Chance, Dr. Coey Bigger, Mr. Bennett (vice Sir Charles Tomes).

Students' Registration Committee.—Sir Norman Moore (Chairman), the President, Dr. Mackay, Dr. Littlejohn, Sir Gilbert Barling, Mr. Sinclair, Dr. Kidd.

The Council then went into committee.

WEDNESDAY, JUNE 2ND.

The Council proceeded to the consideration of penal cases.

TUBERCULOSIS SOCIETY:

A REPRESENTATIVE CONGRESS.

WE briefly announced last week (p. 1197) that under the auspices of this society a two-day Congress was held in Leeds on May 13th and 14th, with additional meetings at Bradford and Harrogate on the 12th and 15th. The Congress was representative of tuberculosis workers from all parts of the country, including Ireland. Dr. H. DE CARLE WOODCOCK (the President) occupied the chair.

Opening Addresses.

On May 13th the proceedings in Leeds were opened with an address by the LORD MAYOR (Mr. T. B. DUNCAN), in which he suggested that social conditions must be improved. Children must be taught to cultivate clean minds and thoughts, and then we might look forward to an A 1 nation, with strong bodies, vigorous minds, and healthy constitutions.—Sir MICHAEL SADLER welcomed the delegates on behalf of the University. We must, he said, develop a fine tradition in industry, family duty and purity, and nobler state of society. These were all factors in the cause we were out to win. —In his presidential address the PRESIDENT advocated more autocratic power for the medical officer of health, the abolition of slums, and the building of new houses which the tubercle bacillus would avoid. Research was needed to show us where we stood.—Professor BENJAMIN MOORE (Medical Research Committee) moved a resolution, seconded by Dr. A. TRIMBLE (Belfast):—

> "That in the opinion of this Congress a conference should take place between those actually engaged in tuberculosis work and those engaged in research work, to arrange the lines on which future investigation should be conducted and the manner in which records should be kept and collated and their results circulated."

After the opening session the delegates were entertained to luncheon by the PRESIDENT.

Sectional meetings began in the afternoon.

Section A.—Tuberculosis and the Workers.

This was the subject of the first section at which Mr. S. SHUTER (H.M. Chief Inspector of Factories) took the chair.—Dr. TRIMBLE thought that tuberculosis was not caused so much by the actual occupation as the terms and conditions under which, and the wages for which, the people worked. Infection took place chiefly in childhood and education was essential to prevent development of the disease in later life. If only the tired worker could obtain the necessary rest 90 per cent. would become automatically cured.—Professor MOORE said that the cost of redeeming those affected with tuberculosis was a sound expenditure. If we could prevent 50,000 deaths a year we would be able to pay the whole war debt in a generation.—Special interest attached to the information given of the evils of the glass-bottle industry by Mr. FISHER (secretary of the Glass-bottle Makers' Society). The blow-pipes used by the men, which are in use 22 out of the 24 hours and pass from worker to worker without sterilisation, being a very probable method by which the disease is transmitted.—Mr. LANCASTER (Typographical Association) and Mr. COHEN (National Union of General Workers) also spoke of the inadequate wages in many trades where the minimum was also the maximum wage. The evils of underground workshops were also mentioned.

Section B.—Tuberculosis and Child Life.

The chair was taken by Mrs. ROBERT HUDSON, who very strongly advocated the attack upon the disease at the very earliest age, and the correction of ailments such as rickets, which were indirectly associated with tuberculosis.—Dr. A. E. L. WEAR (chief medical officer to the Leeds Education Committee) said that in the routine examination of 23,000 children in Leeds 128 cases of pulmonary, 126 glandular, and 66 cases of bone tuberculosis were found. Of 483 crippled children 90 suffered from some form of tuberculosis. Taking all the institutions in the country for tuberculous children together there was less than one place for every 1000 children in attendance. He strongly advocated open-air schools.—Dr. C. W. VINING (Leeds Infirmary) said that he was appalled at the extraordinary amount of chronic ill-health in the second year of life. The chronic catarrhs of early childhood were, he thought, due to defective feeding in the first three years of life. Poverty was not the cause unless it were poverty of commonsense and knowledge. The main defects were want of breast feeding during the first year, and a diet lacking in fat and protein, with excess of carbohydrates during the second year of life.

Section C.—Recent Advances in Treatment.

Dr. MARCUS PATERSON (Collindale Hospital, Hendon) spoke of the value of graduated work, and also deprecated the practice of over-fattening patients and then sending them home to face the rigors of everyday life in an unfit condition. Graduated labour and controlled auto-inoculation ought to be taught in every medical school.—Sir HENRY GAUVAIN (Treloar's Hospital, Alton) spoke of the recent advances in the realm of surgical tuberculosis, and showed lantern slides of the methods adopted.

Section D.—Farm Colony.

Dr. S. JACOB (travelling secretary of the National Association for the Prevention of Tuberculosis) took the chair. He described the limited scope of the sanatorium and the necessity of providing for the convalescent period, where a patient could in an open-air life complete the cure.—Mr. A. G. RUSTON (Lecturer in Farm Economics, Leeds University) spoke of the farming methods which would be most likely to prove successful in a farm colony.—Mr. G. W. ALLEN (chairman of the Association for Tuberculous Ex-service Men in Leeds) put in a strong plea for the establishment of village settlements as distinct from farm colonies, which could only be applicable to a small proportion of the men.

Section E.—The Education and Training of Patients Suffering from Non-Pulmonary Tuberculosis.

In the evening Sir HENRY GAUVAIN gave a lecture on the work at Alton, illustrated by lantern and cinema slides. The Lord Mayor later gave a reception in the City Art Gallery to the delegates.

Friday, May 14th, was devoted entirely to sectional meetings

Section F —Tuberculosis and the Housing Problem

Dr **HALLIDAY SUTHERLAND** (Marylebone Dispensary) said that everything should be done to discourage the growth of cities and to encourage the growth of semi agricultural and semi industrial communities in the country, as in France The widespread ownership of property was the very greatest safeguard against Bolshevism and anarchy —Dr **OSCAR HOLDEN** (M O H , Dewsbury) spoke against consumptives living in back to back houses and urged the segregation of advanced cases He suggested that definite areas should be set apart and patients with their families be put in suitable houses, with workshops provided so that they could earn, at any rate, part of their livelihood —Councillor **NOON** (chairman of the Leeds Housing Committee) stated that there are 73,000 back to back houses in Leeds He advocated new houses being earmarked for tuberculous families —Dr **NOEL BARDSWELL** (London Insurance Committee) deprecated the idea of compulsory segregation, which was impossible for a democratic country

Section G —Sanatorium Dietary and Milk Tuberculosis

The chair was taken by Dr J **JOHNSTON JERVIS** (M O H , Leeds), who spoke of the absolute necessity of a clean milk supply, and this should be the first consideration of the Government —Dr **JANE WALKER** (East Anglian Sanatorium) read a paper on Food Values in Relation to the Treatment in Sanatorium She approved of three main meals a day both for adults and children —Dr **JAMES WATT** (Downs Sanatorium, Sutton) said that surprisingly little special diet was needed in the treatment of tuberculosis —Mr **RUSTON** and Dr **WOODCOCK** contributed a joint paper on the Calorific Values of Foods They advocated a quart of milk a day for each patient as being the best method of obtaining fat

Section H —Surgical Tuberculosis

This turned almost entirely into a discussion of tuberculosis and milk

Mr S W **DAW** (Lecturer in Surgery, Leeds University) said that more than half the cattle in this country gave tuberculous milk because the best milkers were most liable to have the disease —Dr H A **ELLIS** (Middlesbrough) contended that resistance was much more important than infection —Dr F J **HENRY** (Middlesbrough) regretted that experts should be so divided in opinion Research was badly needed, with full collaboration and dissemination of information —Mr **DAW** in reply, upheld the view that prevention was more essential than cure, that milk should be boiled and the vitamines lost replaced by alternative foods

Section I —Tuberculosis and the War

Sir **MONTAGUE BARLOW** (Parliamentary Secretary to the Ministry of Labour) said that approximately 40 000 ex Service men were affected with tuberculosis The Government proposed to erect village settlements for these men, and he was confident that the money would be forthcoming with which to build them —Dr **RAW** said that if the scheme of village settlements could be carried out it would do more than anything else to cure the disease —Dr **BARDSWELL** mentioned that of 430 men discharged with tuberculosis in London 60 per cent were already dead Before settlements could be provided the rest would have shared the same fate

Section J — Care Work

Dr **JANE WALKER** spoke from the point of view of the sanatorium officer She had found great value in the patients club which encouraged them to keep in touch with her after leaving sanatorium She was in favour of employing ex patients on the staffs of institutions —Dr **ELLIS** advocated clubs where tuberculous persons might resort in their leisure hours The whole question of tubercle was the question of after care —Dr F **STANLEY TINKLER** (Surrey) was strongly in favour of local workshops for the employment of ex sanatorium patients This coupled with an energetic educational campaign, would do far more than the scheme of residential industrial colonies which could but touch the fringe of those needing assistance —Dr C L **WILLIAMS** (Dewsbury) thought that attention should be specially concentrated on the pre tuberculous and the early case —A resolution was passed advocating the initiation of a well organised and adequate scheme of after care in connexion with the medical treatment of the disease, either by the Government or the local authorities

Section K —Artificial Pneumothorax

Dr **MORRISTON DAVIES** (Vale of Clwyd Sanatorium) gave an address on the Methods of Collapse Therapy, which was illustrated by lantern slides of X ray photographs —Dr S **VERE PEARSON** (Mundesley Sanatorium) described the types of cases treated and results obtained —Dr Z P **FERNANDEZ** (Armley Hospital, Leeds) also spoke

Section L —Tuberculosis and Training of the G P

Dr J **KAY JAMIESON** (Professor of Anatomy, Leeds University) took the chair and urged the study of tuberculosis on wide lines —Dr J **LE FLEMING BURROW** (Tutor in Medicine, Leeds University) referred to the political cry for nationalisation He deprecated this because it discouraged initiative and research Whole time service was not beneficial, and a multiplication of special whole time officers was not advisable He urged that more should be spent on research and less on treatment, in this way the object would be obtained more easily Many delegates in the evening visited Killingbeck Sanatorium and Armley Hospital, when a demonstration in artificial pneumothorax was given

Section M

An address was given, illustrated by kinematograph films, by Dr **HALLIDAY SUTHERLAND**, on Consumption its Cause Cure, and Prevention

INTERNATIONAL ASSOCIATION OF MEDICAL MUSEUMS

REPORT OF MEETING OF THE AMERICAN AND CANADIAN SECTION

(FROM A CORRESPONDENT)

THIS society held its thirteenth annual meeting at Cornell University Medical College New York Professor O Klotz of Pittsburg, in the chair when Dr Roy Miner, Associate Curator of the American Museum of Natural History, New York, was present as delegate from the *American Association of Museums*

The programme was opened by addresses delivered by the Chairman and Dr Maude E Abbott on The Pathological Collections and the Activities on Behalf of the Medical Museum and of this Association of the late Sir William Osler which were received with deep appreciation

A report on *The Central Bureau for North America for the Preservation of Microscopic Results of Medical Research* which was established by the Association some years ago but has not yet been operated for lack of funds was presented by Leo Loeb of St Louis Mo urging the *importance of this Bureau and* the necessity for its immediate operation and a resolution was passed authorising the Council to take steps to attempt to obtain a fund for the operation of this Bureau and the adequate publication of the bulletins as a *complete* Index Pathologicus

The Canadian National War Museum gave two important contributions Museum Records Illustrating Facial War Injuries demonstrated by Major F F Risdon of Toronto and Lantern Slides from Water-colour Paintings showing the Canadian Army Medical Arrangements at the Front by Major G A Campbell of Ottawa and a smaller exhibit of Pathological Specimens showing *Bacillus Aerogenes* Infections following Gunshot Wounds by Major F B Gurd of Montreal

Professor James Ewing of Cornell showed a large series of tumours of bone which included some unusual forms of cell neoplasm F S Jackson of Montreal communicated notes on a new preservative fluid (formalin-sugar acting by absorption) for delicate specimens and W M L Coplin of Philadelphia a new method for the permanent mounting of Kaiserling specimens without immersion in fluid *which promises to be of much technical* value

Other items of interest were a detailed study by Dr Ira G Dyar of Washington on the technique of the Preservation of Serial Sections of the Brain and Cord for Microscopical Study *Note on* the Preservation of an Amyloid Spleen by William Boyd of Winnipeg The Teaching Value of the Small Museum Specimen by O Klotz of Pittsburg A Method for Prolonged Preservation of Stock Cultures *of Bacteria* by *Homer F Swift of New York*

"Demonstration Exhibit of Organism, Cultures, and Lesions in Acute Epidemic Encephalitis (Lethargica)," by Leo Loewe and Israel Strauss, of New York; "Stereoscopic Pictures of Dissections of the Actual and Accessory Muscles of the Eye," by S. E. Whitnall, of Montreal; "Dissection of a Case of Duplication of Œsophagus, Stomach, and Small Intestine, the Second Œsophagus communicating with Blind End of Foregut at Back of Neck," by A. C. Freedman, of Montreal; "Sympus Apus and Bipus," by S. Chelliah, Madras, India.

The following officers were elected for the ensuing year: President: W. M. L. Coplin, Philadelphia. Vice-Presidents: James Ewing, New York; Howard Karsner, Cleveland; H. E. Robertson, Minneapolis. Councillors: A. S. Warthin, Ann Arbor; O. Klotz, Pittsburg; R. A. Lambert, New Haven; C. F. Silvester, Washington, D.C.; W. G. MacCallum, Baltimore; Lawrence Rhea, Montreal. Secretary-Treasurer: Maude E. Abbott, Montreal. Assistant Secretaries: L. Gross, Montreal; H. Goldblatt, Cleveland.

Annual Exhibition.

The annual exhibition of the society of material illustrating papers upon the programme of this Association and of the Association of Pathologists and Bacteriologists was held also at Cornell on April 1st and 2nd for the benefit of both societies, and presented an attractive and comprehensive scientific display, which was largely attended and much appreciated.

Among the exhibits presented by the American Association of Pathologists and Bacteriologists were the following:—"Coarctation of the Aorta with Bicuspid Aortic Valve and Rupture of the Aorta," by Harry Goldblatt of Cleveland; "An Endothelial Leukocytosis by Injection of Saprophytic Tubercle Bacilli," by F. J. McJunkin of Milwaukee; "Tissue Reactions to Tubercle Waxes," by Plinn F. Morse of Detroit; "Glomerular Lesions in the Healed (Abacterial) Stage of Chronic Bacterial Nephritis," by George Baehr, of New York; "Monocytic Leukæmia," by N. Rosenthal, of New York; "Observations in Experimental Histogenesis of Experimental Tubercles in the Lungs of Vitally Stained Rabbits," by H. Chandler-Foot, of Boston; "Metaplasia so Illustrated in Leukoplakia of the Pelvis of the Kidney," by De Wayne G. Richey, of Pittsburg; "Defects of the Aortic Septum in Explanation of Congenital Aneurysms of the Right Aortic Sinus of Valsalva, with Associated Interventricular Septal Defect," by Maude E. Abbott, of Montreal; "Bone Syphilis in the Rabbit," by Louise Pearce and Wade H. Brown, of New York.

URBAN VITAL STATISTICS.

(Week ended May 29th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 13·8, 13·8, and 13·2 in the three preceding weeks, further declined to 12·8 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 12·1, or 0·1 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 3·3 in Hornsey, 5·4 in Enfield, and 6·6 in Ilford, to 19·3 in Middlesbrough, 25·5 in West Hartlepool, and 26·5 in Sheffield. The principal epidemic diseases caused 275 deaths, which corresponded to an annual rate of 0·8 per 1000, and comprised 108 from measles, 61 from infantile diarrhœa, 45 from whooping-cough, 40 from diphtheria, 15 from scarlet fever, and 6 from enteric fever. Measles caused a death-rate of 1·8 in Leicester, in Wigan, and in Newport (Mon.), 1·9 in Dudley, 2·5 in Acton and in Blackburn, and 2·6 in Rhondda. The deaths from influenza, which had been 201, 216, and 211 in the three preceding weeks, further fell to 188, and included 77 in Sheffield, 26 in London, 12 in Manchester, and 6 in Rhondda. There were 1797 cases of diphtheria and 1703 of scarlet fever under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 1894 and 1734 respectively at the end of the previous week; the last remaining case of small-pox was discharged during the week. The causes of 31 of the 4380 deaths in the 96 towns were uncertified, of which 9 were registered in Birmingham, and 3 in Manchester.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 18·4, 16·9, and 15·6 in the three preceding weeks, further declined to 14·2 per 1000. The 316 deaths in Glasgow corresponded to an annual rate of 14·8 per 1000, and included 10 from measles, 8 from influenza, 4 from diphtheria, 2 each from small-pox and infantile diarrhœa, and 1 each from scarlet fever and whooping-cough. The 92 deaths in Edinburgh were equal to a rate of 14·1 per 1000, and included 3 from infantile diarrhœa and one each from measles and scarlet fever.

Irish Towns.—The 152 deaths in Dublin corresponded to an annual rate of 19·1, or 2·4 per 1000 below that recorded in the previous week, and included 12 from whooping-cough, 7 from measles, 6 from infantile diarrhœa, 4 from influenza, and 2 from diphtheria. The 122 deaths in Belfast were equal to a rate of 15·4 per 1000, and included 3 from influenza, 2 each from measles, scarlet fever, and infantile diarrhœa, and 1 from enteric fever.

Correspondence.

"Audi alteram partem."

REPORT OF THE CONSULTATIVE COUNCIL: COÖPERATION OF RED CROSS.

To the Editor of THE LANCET.

SIR,—The report issued by the Consultative Council of the Ministry of Health (THE LANCET, May 29th, p. 1183) embodies recommendations which will necessarily entail a considerable increase in the work of transport of the sick and injured in this country, and the Council draw special attention to the necessity for an ambulance service.

I am happy to say that the Joint Council of the British Red Cross Society and the Order of St. John has been able to anticipate this demand and has, during the past 12 months, established over 300 motor ambulance stations throughout the country. That the need existed for an efficient ambulance service even before the establishment of the system of linked hospitals foreshadowed in the report, is shown by the fact that though a large proportion of the ambulances have been in service for only a few months they have already been the means of transporting over 12,000 cases.

The administration of our ambulances has been delegated through county directors to local organisations or public health authorities as circumstances dictated, but central control of the service is maintained at headquarters, and we are thus in a position to develop and extend the scheme on such lines as may prove most desirable to meet the needs of a coördinated health service.—I am, Sir, yours faithfully,

ARTHUR STANLEY,
Chairman, Joint Council, British Red Cross Society and Order of St. John.

19, Berkeley-street, W., May 29th, 1920.

THE STANDARDISATION OF COLOUR PERCEPTION.

To the Editor of THE LANCET.

SIR,—I do not wish in any way to depreciate Dr. Edridge-Green's work on colour vision, but I think that if, as is very possible, his work has been undervalued in the past, the pendulum has now swung in the opposite direction, and the work of others is being unjustly depreciated in his favour. Your own review of his book (THE LANCET, May 29th) is an appreciation which adopts a much more judicial attitude than is found in some other reviews which have appeared, and it is because I am convinced that it is the aim of THE LANCET to establish scientific truth and be just to all that I venture to hope that you will allow me to make a few remarks on one or two of your statements.

You attribute to Dr. Edridge-Green "the removal of the colour-discriminating faculty from the retina, where the theories of Helmholtz and Hering would place it, to the brain." When we remember that Helmholtz in his Physiologische Optik proved himself no mean psychologist, as well as mathematician and physicist, that Hering in his Lehre vom Lichtsinn treats specially the psychological aspects of the problem, and that numberless physiologists and psychologists have been more or less staunch adherents to one or other of the theories propounded by these authors, it is clear that these theories by no means ignore the part which the cerebral apparatus plays in the perception of colours. Dr. McDougall's papers in *Mind*, for example, deal profoundly with the cerebral apparatus of colour vision, and have received far less attention than is due to them. Von Kries, following Donders and A. Fick, quite definitely regards the three components theory as only a partial explanation, applicable, indeed, chiefly to the events taking place in the peripheral mechanism, which events are modified and transformed in the higher visual centres (theory of zones). That the events which occur in the peripheral apparatus of vision and audition are more complex than in any other sense organ would be admitted by Dr. Edridge-Green, and is, indeed, asserted in his writings, and I imagine every psychologist would predicate important modifications of the nervous impulses in the cerebral centres, and some portion of the cortex as the sole nervous mechanism concerned in the conscious appreciation of the transformed impulses.

With regard to tests for colour-blindness I freely admit that I have personally adopted a perhaps too cautious and conservative attitude to innovations. Considerable experience in testing for colour-blindness has convinced me that the Holmgren wool-test is better discarded—not because it is so faulty as has been stated, but because it requires great experience on the part of the examiner and more intelligence than is to be expected of the examinee. Moreover, it is inherently objectionable to sailors and railway-men. But I would also point out that it is very easy for incompetent examiners to pass seriously colour-blind men with Dr. Edridge-Green's colour-perception lantern. I quite agree that it is a good test in the hands of an expert examiner, but prolonged experience has shown that the Board of Trade lantern is better, because it is more "fool-proof." If the Board of Trade had not adopted the unwise policy of disallowing the commercial exploitation of their lantern, I feel sure that it would have been generally used. The principles of this lantern were published in the report of the Departmental Committee on Sight Tests, and I am surprised that no one has put a lantern of this design on the market. If I had not been intimately connected with the Board of Trade examinations I should long ago have endeavoured to get this done.

I fear I have already trespassed upon your courtesy. I will only add that, although controversy in the press is thoroughly repugnant to me, I propose to deal more in detail with Dr. Edridge-Green's theories of vision elsewhere. I am, Sir, yours faithfully,

J. HERBERT PARSONS.

Queen Anne-street, Cavendish-square, W., May 29th, 1920.

ANOMALOUS VARIOLOID DISEASE.

To the Editor of THE LANCET.

SIR,—In dealing with cases such as reported by Dr. W. Allingham, and referred to in your editorial note of May 29th (p. 1179), the peril of delaying a diagnosis is obvious, and equally so is the difficulty of those responsible in giving a definite opinion with desirable quickness. Dr. Allingham would solve the problem by requiring "isolation of chicken-pox for 10 days." But it is not apparent that this would do more than provide time for much professional contention by local practitioners favouring opposite opinions, whilst case after case appeared without decisive classical signs—a state of affairs well illustrated on the first appearance of the "mild type" of small-pox in Australia in 1913. The Leicester school makes this difficulty the chief doctrine of its practice in not urging infantile vaccination—unmindful of possible mortality—so that the practitioner may have the advantage of demonstrations of unmodified small-pox! This is a method of facilitating diagnosis which, happily, is not likely to find much favour beyond the confines of Leicester. Hence, I venture to make an addition to Dr. Allingham's useful suggestion which could be put in force at once by notifying selected existing laboratories throughout the country, and would be easy of adoption on coming into force of the recent scheme of the Ministry of Health for "Medical and Allied Services"—namely, isolation of cases of suspected varicella or small-pox pending a decision arrived at in the laboratory of a "Secondary Health Centre." Here the allergic test in rabbits previously sensitised by anti-smallpox vaccine could be employed. According to Dr. John Nivison Force and Helen Howell Beckwith[1] on intradermal inoculation of the contents of the dubious vesicles, a diagnosis of variola may be arrived at if there be a cutaneous reaction within 48 hours. Probably the reaction would be more readily demonstrable were calves used instead of rabbits. It will be remembered that the laborious experiments by Dr. W. G. Armstrong,[2] Senior Medical Officer of Health, New South Wales, associated with Dr. Burton Cleland and Dr. E. W. Ferguson, have removed all doubts so far expressed that the American "mild type" of small-pox imported to Australia, and which I think it more reasonable to dub the "amaas strain" (and thus relieve our cousins from being regarded as the *fons et origo mali*), is of the nature of variola. On the other hand, W. Stoelzner[3] has shown that in an epidemic of varicella during the war the type was so virulent that, both in regard to constitutional symptoms and character of the vesicles, there was a close resemblance to variola.

I am, Sir, yours faithfully,

W. G. KING,

May 29th, 1920. Colonel, I.M.S. (Ret.)

To the Editor of THE LANCET.

SIR,—Referring to the annotation on Anomalous Varioloid Disease in your issue for May 29th, and to the paper by Dr. W. Allingham in the same issue, to which you refer, it may be of interest to state that I had the opportunity of seeing, in consultation, not only Dr. Allingham's cases, but also a further series of cases directly related to them which subsequently came under observation at West Ham. The infection was conveyed by the son of one of the Orsett cases, who visited his father at Grays for three days, during which time father and son slept in the same bed. This man and seven children have all since been attacked by the disease.

There can, in my opinion, be no doubt but that the type of the disease with which the Orsett and West Ham cases have been affected is similar to that experienced in the earlier outbreak to which you refer as having been investigated recently by myself in a limited area on the borders of Norfolk and Suffolk. In both outbreaks the symptoms and general course of the disease more nearly resembled those of alastrim than of typical small-pox.

I am, Sir, yours faithfully,

May 31st, 1920. S. MONCKTON COPEMAN.

THE CLINICAL DIAGNOSIS OF DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—Whilst recognising fully the value of Dr. H. Drinkwater's observations on the naked-eye appearance of the fauces in diphtheria, there are a few points where danger to the patient would arise if they are relied upon—as the trend of his article seems to me to suggest—as an alternative to bacteriological investigation of the lesion.

(*a*) "In diphtheria the patch is raised above the level of the mucous membrane." Here the danger lies in eliminating coexistent scarlet fever and diphtheria, where the lesion frequently consists of a loss of surface without any raised deposit, and is followed by diphtheritic toxæmia and paralysis. Such cases are commonly seen on admission to every large fever hospital.

(*b*) "If the deposit is single in each affected area the disease is either diphtheria or Vincent's angina ...... in the period of growth." This feature, whilst useful in children, is fallacious in adults. Repeatedly have I seen true diphtheria on the first day of the disease (in nurses especially) with a distribution of the deposit indistinguishable from that of follicular tonsillitis.

(*c*) It is a pity that Dr. Drinkwater's paper makes no allusion to scarlet fever. In children this complaint may give rise to faucial appearances over-riding every one of the postulates in his paper, and is in practice *the* disease in which the differential diagnosis is most important.

(*d*) "A bacteriological examination may mean a delay of 24 or 48 hours, with possibly disastrous results." Certainly, if the criminal mistake is made of waiting for the result before segregating the patient and administering antitoxin. But does any careful practitioner do this nowadays?

If Dr. Drinkwater's precepts are largely followed I think that the uncomfortable—and sometimes tragic—occurrence in convalescence of diphtheritic heart failure or paralysis in a patient whose case had been
as non-diphtheritic, will be much more freque
it now is. Moreover, many of these cases of "t

may also peel and develop scarlatinal nephritis! The danger lies not in Dr. Drinkwater's relying on his own skilled eye and careful observation, but in others attempting to follow him without bacteriological assistance; hence the warning note in this letter.

I am, Sir, yours faithfully,
A. KNYVETT GORDON,
Formerly Medical Superintendent of the Manchester City Fever Hospital and Lecturer on Infectious Diseases in the University.
Bedford-square, W.C., May 31st, 1920.

To the Editor of THE LANCET.

SIR,—Dr. H. Drinkwater's article in your columns last week upon the diagnosis of diphtheria and throat exudations is one of those things that make the reader ask if it is not too good to be true. The author may have deceived himself, even while we admit the obvious sincerity of his observations as well as the good opportunities which he enjoyed while making them.

If Dr. Drinkwater's experience proves to be borne out by other physicians, clinical observation will be greatly in his debt. I am, Sir, yours faithfully,

May 29th, 1920. A VETERAN.

THE SURGICAL TREATMENT OF UTERINE AND VAGINAL PROLAPSE.

To the Editor of THE LANCET.

SIR,—In your issue of May 15th my friend, Dr. W. E. Fothergill, complains that my interpretation of his words is not correct. I greatly regret that I should have misunderstood them, for they are quite clear; but, perhaps, by so doing I shall prevent everyone who reads the same words from falling into a similar error. Nevertheless, the views expressed in my lecture remain unchanged in regard to the importance of puerperal retroflexion and the necessity of curing the condition. I do not think Dr. Fothergill really holds strong views to the contrary: I have too high a regard for his opinion and experience.

What we want, Sir, are facts and figures, not nebulous mental impressions. This is very evident when one peruses the long mystic letter of Mr. R. H. Paramore. He is subversive without being destructive. He uses strange and obscure phrases, such as: "But this pelvic floor is for him (W. B. B.) apparently a visceral structure." I confess I may be wrong in my conception of the meaning of this statement. If Mr. Paramore intends to imply that I consider the musculature of the utero-sacral and utero-pubic "ligaments" visceral he is right in so far as the uterus is a viscus, and these muscle-bundles, like the muscle-fibres in the round "ligaments," are morphologically continuous with the external coat of the uterus. But, earlier in this letter, he states: "(W. B. B.) pays no attention to the musculature occluding the outlet; and in his surgical treatment limits himself for the most part to visceral structures, as though this musculature did not exist and is not concerned with the genesis of prolapse."

I mentioned—as Mr. Paramore recognises—that I could not in one lecture discuss every aspect of the subject, adding, "but it goes without saying that much can be accomplished in the way of prophylaxis, and that all surgical procedures are based on a correct appreciation of the normal anatomical conditions and on the lesions present in prolapse." By prophylaxis was meant, as any one should know, not only the non-operative and operative treatment of puerperal retroflexion, but also the careful conduct of labour.

If Mr. Paramore will turn to p. 42, et seq., of the third edition of my "Principles of Gynæcology," he will find I have taken some trouble to describe—briefly, and I hope intelligibly—the musculature of the pelvic outlet; and, if he will glance at the section on operative procedures, he will observe how much I *am* concerned with the musculature, without, I hope, being tedious. Moreover, it will please Mr. Paramore to find, in the appropriate section, such headings as "The acquired form of *hernial* prolapse" and "Other *herniæ* of the uterus" (*italics here to indicate the important word*), and so on *ad nauseam*, as Dr. Fothergill would say.

I think, Sir, the time has come when we should be glad to have Mr. Paramore's methods and figures in regard to the no doubt very large number of cases of prolapse on which he has operated. I imagine, from the way he writes, that they are far superior to my own or those of anyone else. Once a student always a student, I shall, therefore, be only too willing to learn from anyone how to reach "the zenith," and how better to cure prolapse than by the methods I practise; but I beg Mr. Paramore, or whoever my mentor is to be, in order to save time, to select for the demonstration a case of "congenital" procidentia, not to use paraffin to increase the "viscosity of the visceral parts concerned"—another strange phrase of Mr. Paramore—and to let me see the result 18 months after the "wave of the hand," or whatever the procedure may be. I shall be glad to return the compliment at any convenient time. I am, Sir, yours faithfully,

Liverpool, May 31st, 1920. W. BLAIR BELL.

PS.—I do not think Mr. Paramore need be anxious about his interposition case that had a fibroid in the uterus. Any competent surgeon who, in the event of further trouble, has to deal with the matter will thank him for making the uterus so accessible.

To the Editor of THE LANCET.
